

# The Content of Different Hydrogen Bond Models and Crystal Structure of Eucalyptus Fibers during Beating

Longting Yuan,<sup>a,b</sup> Jinquan Wan,<sup>b,c,\*</sup> Yongwen Ma,<sup>b,c</sup> Yan Wang,<sup>b,c</sup> Mingzhi Huang,<sup>b,c</sup> and Yangmei Chen<sup>d</sup>

Different hydrogen bond and crystalline cellulose structure models of eucalyptus fibers were studied by Fourier transform infrared spectrometer (FTIR), X-ray diffraction (XRD), and Cross-Polarization Magic Angle Spinning Carbon-13 Nuclear Magnetic Resonance (CP/MAS <sup>13</sup>C NMR). It was shown that when the beating time was increased from 5 to 15 min., the content of inter-molecular hydrogen bonds, O(6)H···O3', increased by 11.2% as measured by FTIR. However, the content of the inter-molecular hydrogen bonds decreased quickly as the beating time was increased from 15 to 25 min. Meanwhile, the contents of the intra-molecular hydrogen bond, O(2)H···O(6) and O(3)H···O(5), changed from 8.25% to 8.18% and from 39.33% to 31.27%, respectively, when the beating time increased from 5 to 15 min. The content of the intra-molecular hydrogen bonds increased quickly with the further increase in the beating time. It was shown by XRD that there was a little difference in the average width of crystallite size in the (002) lattice plane when the beaten time was between 5 to 25 min. Non-linear fitting of the cellulose C4 region of the <sup>13</sup>C CP/MAS NMR showed that the average lateral fibril aggregate dimensions and the content of different cellulose polymorphs changed during beating.

## INTRODUCTION

It is well known that wood is an abundant, a renewable, and a biodegradable composite with many useful applications, such as papermaking, building and furniture construction, and as a natural reinforcement aid in polymer composites (Jiménez *et al.* 2006; Baratieri *et al.* 2008; Lorenzo *et al.* 2009); however, tropical deforestation is an expanding global issue (Sodhi *et al.* 2010; Zhai *et al.* 2012); thus recycled cellulose has become a significant fiber source (up to 70%) for papermaking at the end of the 21st century (Wan and Ma 2004). So, it is very important to study the properties of cellulose fiber and find methods to improve recycled cellulose fiber properties. At present, most chemical and biological methods that improve the quality of the fiber can increase papermaking costs and can have environmental related issues (Blomstedt and Vuorinen 2007; Cao and Tan 2004; Pala *et al.* 2001). There are many changes of the characteristic

of cellulose fiber significantly formed into a wet web of paper when cellulose fiber is subjected to such processes as pressing, drying, printing, storage, and deinking. In order to find more effective ways for addressing the above mentioned problems and efficiency limitations with unbleached kraft pulps, this study investigated an approach of beating to modify eucalyptus fibers.

Plant cellulose fibers have complex composite structures that are mainly composed of cellulose, lignin, and hemicelluloses (Liu *et al.* 2008). Cellulose is the most common component found in the cell walls of higher plants. Typically, it is a high molecular weight linear polymer composed of  $\beta$ -D-glucopyranose units linked by (1 $\rightarrow$ 4)-glycosidic bonds. It is the nature of this polymer to form a long, flat polymer chain that exposes a number of hydroxyl groups and hydroxyl bonding sites, allowing the polymer chain to form a large amount of hydrogen bonds, leading to a crystalline structure (Gümüskaya *et al.* 2003). Native cellulose is known to be a composite of two distinct crystal types, namely  $I_{\alpha}$  and  $I_{\beta}$ , whose fractions vary depending on the origin of the cellulose sample (Duchesne *et al.* 2001; Hult *et al.* 2003). Several studies have been undertaken to investigate the nature of the changes in cellulose superstructure. Crystallinity has an important effect on the physical, mechanical, and chemical properties of cellulose. For example, with increasing crystallinity, the tensile strength and dimensional stability decrease, while properties such as chemical reactivity and swelling decrease (Chen *et al.* 2010). As is well known, several techniques have been developed for determining the cellulose crystallinity and fibril aggregate dimensions, which include X-ray diffraction (XRD), solid-state  $^{13}\text{C}$  nuclear magnetic resonance ( $^{13}\text{C}$  NMR) (Park *et al.* 2010; Miyamoto *et al.* 2011; Hult *et al.* 2002), and Fourier transform infrared spectroscopy (FTIR) (Mohkami and Talaeipour 2011; Liu *et al.* 2005). Furthermore, the hydrogen bonding network of cellulose has been studied with the application of infrared spectroscopy, and the hydrogen bonding region of the infrared absorptions has been almost completely assigned (Li *et al.* 2009; Maréchal and Chanzy 2000). Similarly, some authors have used Fourier transform infrared spectroscopy (FTIR) analysis to characterize the different hydrogen bond models of cellulose crystallinity. They concluded that the intra-molecular hydrogen bonds for O(2)H $\cdots$ O(6) and O(3)H $\cdots$ O(5), and the inter-molecular hydrogen bonds for O(6)H $\cdots$ O(3') in cellulose I appear at 3455–3410  $\text{cm}^{-1}$ , 3375–3340  $\text{cm}^{-1}$ , and 3310–3230  $\text{cm}^{-1}$ , respectively (Oh *et al.* 2005; Popescu *et al.* 2009). However, the content of the hydrogen bond and the details about the eucalyptus cellulose allomorphs during beating were not reported.

Eucalyptus pulps contain short fibers that are easily beaten. Beating is the most important physical treatment carried out on pulp before papermaking; it highly affects the physical properties of the paper and might be considered to be the first step in their “activation”. It increases the area of contact between the fibers by increasing their surface area through fibrillation and by increasing their flexibility. For instance, the effect of beating on the changes of recycled eucalyptus fibers in morphological parameters, properties, crystal structure of cellulose, and pore structure of cellulose fiber were analyzed using FTIR and low-temperature nitrogen absorption by Chen *et al.* (2012). Ruel *et al.* (1978) used transmission electron microscopy (TEM) and scanning transmission electron microscopy (STEM) to study the structure of cellulose fibers. It is clear that any treatment of the wood material that removes constituents by breaking covalent bonds, as in chemical pulping, or by breaking physical bonds, as in mechanical treatments, will induce more or less modifications in the morphology (Kure and

Dahlqvist 1998) and the super-molecular organization of the fiber wall (Duchesne 2001; Billosta *et al.* 2006). These alterations may have a positive or negative effect on the fiber properties. Ibrahim *et al.* (1989) also studied the relation between fiber crystallinity and the properties of paper during beating. However, very little research has been carried out on the super-structure, especially regarding different hydrogen bonds of various cellulose crystalline types. Accordingly, it is important to study the super-structural changes in the eucalyptus fibers, with the broader aim at determining the content of different cellulose polymorphs during beating.

The goal of the present study was to analyze the ultra-structure of eucalyptus fibers and to illustrate the existence of hydrogen-bond in greater detail through the CP/MAS  $^{13}\text{C}$  NMR analysis of cellulose in conjunction with X-ray diffraction and infrared spectrometry measurements using PeakFit software. The results of this investigation provided reliable data through peak-fitting analyses (Chen *et al.* 2004). The broader objectives of this work were to assess the contribution of beating to cellulose super-structural changes.

## EXPERIMENTAL

### Materials

Eucalyptus wood chips were cooked in autoclaves according to the conventional kraft process under the following conditions: 17% NaOH and 5%  $\text{Na}_2\text{S}$ , wood-to-liquor of 1:4, time-to-temperature of 2 h, cooking temperature of 170°C, and time at cooking temperature of 2 h. The moisture content of unbleached wet eucalyptus pulp was 82.79% by weight in the never-dried state.

### Methods

#### *PFI beating and papermaking*

PFI beating was carried out in accordance to TAPPI Test Method T248 wd-97 with the following conditions: pulp consistency 10%, bedplate-roll gap of 0.3 mm, bedplate speed 1400 r/min., and roll speed 1460 r/min. Different times were recorded. Handsheets were made on a Rapid-Köthen Sheet Former in accordance to TAPPI standards. The grammage of the unbleached eucalyptus handsheets was 60 g/m<sup>2</sup>. Some handsheets were placed in a humidity-controlled room in accordance to TAPPI Test Method T402 and tested for physical properties 24 h later. Other handsheets were soaked in deionized water for at least 8 h. The rewetted handsheets were then disintegrated for 5000 revolutions in a laboratory disintegrator. Then the repulped fibers were remade into handsheets and dried accordingly to the described procedure above.

#### *Fourier transform infrared spectrophotometer (FTIR)*

The powdered cellulose and subsequently dried KBr were sifted through a 200-mesh screen. Cellulose (3.5 to 4.0 mg) and KBr (350 mg) were placed in an agate mortar, well-mixed and pulverized. The mixture was dried at 60°C for 4 h and then poured into a tableting mold to form transparent tablets. Spectra were recorded using a Bruker Vector 33 Fourier Transform Infrared Spectrophotometer (FTIR) set at a resolution of 4 cm<sup>-1</sup> over the range 4000-400 cm<sup>-1</sup>. For a better understanding of the structure of the samples, deconvolution of the spectra was carried out by using PeakFit software in combination

with Gaussian distribution function (Marechal *et al.* 2000; Oh *et al.* 2005; Popescu *et al.* 2009). The correlation values of the deconvolutions fitting was  $r^2 \geq 0.99$ ; therefore, the use of this function is a good approach. The fitting curve matches the experimental curve very well. After deconvolution, the FTIR spectra region of 3800 to 3000  $\text{cm}^{-1}$  was resolved into three or four bands. The absorbance of the band obtained from a local baseline fitting was automatically calculated at the maximum absorbance found by using the sensitivity of the PeakFit software.

#### *Determination of cellulose crystallinity by X-ray diffraction (XRD)*

The X-ray diffraction (XRD) scattering pattern of the pulp was analyzed on a Philipps X'Pert MPD diffractometer using a Cu-K $\alpha$  source ( $\lambda = 0.154$  nm) in the  $2\theta$  range of 4 to 60° and a scanning step width of 0.02°/scan. Each analysis was repeated in triplicate. The other scattering was subtracted from the pulp diffraction diagram. The crystalline reflections and amorphous halo were defined according to previously described recommendations (Wan *et al.* 2010 and Liao *et al.* 2011). The degree of cellulose crystallinity (%) and the average width of the crystal in (002) lattice plane were calculated as the following equation (Kim and Hotzapple 2006):

$$\text{CrI} = \frac{I_{002} - I_{\text{am}}}{I_{002}} \times 100 \quad (1)$$

where  $I_{002}$  and  $I_{\text{am}}$  are the scattering intensities from the diffraction intensity of (002) plane and the diffraction intensity at  $2\theta=18^\circ$ , respectively;

$$L_{002} = \frac{K \lambda}{\beta_{\theta} \cos \theta} \quad (2)$$

where  $\beta_{\theta}$  is the width of the middle height of the (002) reflection;  $\theta$  is the maximum of the (002) reflection, in radians;  $\lambda$  is the wave length of the X-ray source (0.154 nm); and  $K$  is the Scherrer constant (0.9).

The spectra were deconvolved using Gaussian mixed with Gaussian-Lorentzian profiles. After deconvolution, the several parameters can be calculated (He *et al.* 2007; Heinze and Liebert 2001), and the crystalline index and apparent crystallite size was obtained.

#### *Sample preparation for CP/MAS $^{13}\text{C}$ NMR*

The pulps for  $^{13}\text{C}$  NMR analysis were subjected to a mild chlorite delignification with  $\text{NaClO}_2$  (1.5 g / g sample) under acidic conditions at room temperature followed by treatment with 0.1 M NaOH overnight. Between the  $\text{NaClO}_2$  and NaOH stages, the samples were rinsed with deionized water to pH 4-5. The overall procedure was repeated twice. Afterwards, the samples were then hydrolyzed for 8 h in 2.5 M HCl at 100 °C (Hult *et al.* 2001), and washed with deionized water to a pH of 4-5 prior to drying freely.

#### *Determination of NMR spectroscopy*

The spectra of all samples (water content 40 to 60% by weight) were recorded on a Bruker AVANCE AV 400 instrument (at ambient temperature) operating at 7.04 T for  $^{13}\text{C}$  NMR. The pulp samples were packed in a zirconium oxide rotor. The MAS rate was 4-5 kHz. The CP/MAS  $^{13}\text{C}$  NMR data was acquired with a CP pulse sequence using a 3.5 ms proton 90° pulse, 800 ms contact pulse, and a 2.5 s delay between repetitions.

## RESULTS AND DISCUSSION

### Changes of Functional Groups of Eucalyptus Cellulose Fibers during Beating

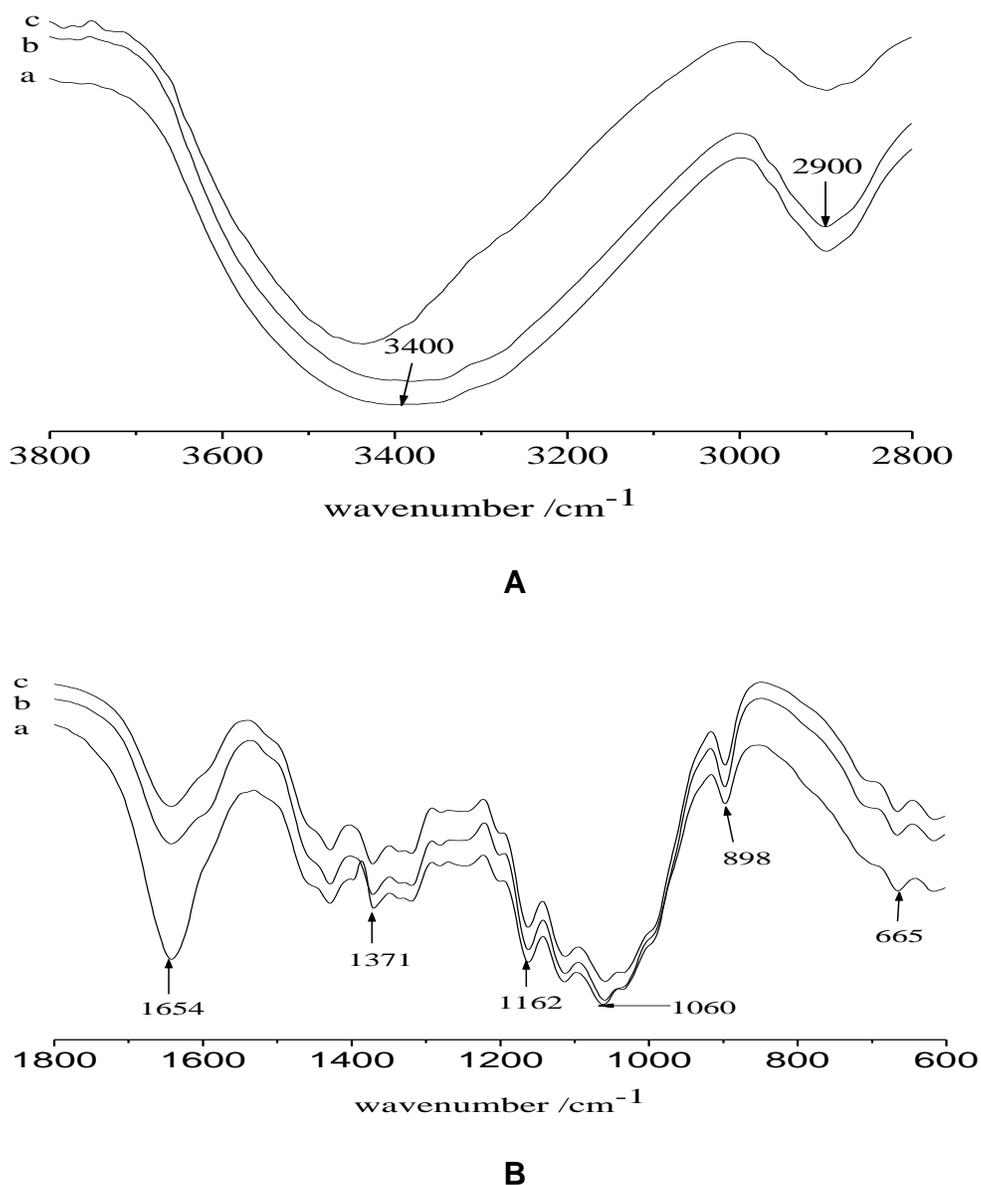

Infrared spectroscopy, which is known to be sensitive to certain structural features, has had a long tradition in wood research. The two information-rich regions of the FTIR spectra of the eucalyptus fibers were  $3800\text{ cm}^{-1}$  to  $2800\text{ cm}^{-1}$  and  $1800\text{ cm}^{-1}$  to  $600\text{ cm}^{-1}$ , as shown in Figs. 1 A and B, respectively. The absorption bands and the corresponding structure assignments for the infrared spectra were reported in previous articles (Wan *et al.* 2010; Chen *et al.* 2011; Poletto *et al.* 2011). Table 1 shows the absorption bands and the corresponding structure assignments from the infrared spectra. The band in the range of  $1700\text{ cm}^{-1}$  to  $1550\text{ cm}^{-1}$  may be associated with water absorption. The band in the range of  $1430\text{ cm}^{-1}$  can be assigned to the HCH and OCH in-plane bending vibration, and  $1365\text{ cm}^{-1}$  assigned as the in-plane CH bending may be from hemicellulose or cellulose, respectively.

**Table 1.** Infrared Spectra Adsorption and Structural Assignment

Wavenumber ( $\text{cm}^{-1}$ )	Assignment
3350	Intra-molecular OH stretching vibration
2900	CH, $\text{CH}_2$ and intermolecular OH stretching vibration
1637	Adsorbed water and oxygen-containing group
1432	HCH and OCH in-plane bending vibration.
1372	Cellulose and hemicelluloses CH bending vibration
1163	Cellulose and hemicelluloses C-O-C stretching vibration
1058 -1060	Cellulose and hemicelluloses C=O stretching vibration
898	$\beta$ - glycosidic bond vibration

Figure 1 shows the FTIR spectra of eucalyptus pulp. From top to bottom, the spectra are those for pulps that have been refined for 25 min, 15 min, and 5 min, respectively. Despite the absorbance intensity changes, wave number shifts are also shown for the bands at  $1643 \rightarrow 1654 \rightarrow 1660\text{ cm}^{-1}$ ,  $2900 \rightarrow 2898 \rightarrow 2900\text{ cm}^{-1}$ , and  $3406 \rightarrow 3379 \rightarrow 3436\text{ cm}^{-1}$  (higher wave number with lower absorbance), so in the region of the FTIR spectra, some bands exhibited little differences. Additionally, seen from these three samples in Fig. 1, a broad band can be observed at the  $3600\text{ cm}^{-1}$  to  $3200\text{ cm}^{-1}$  region, which was attributed to the stretching of the hydroxyl (OH) groups, at the  $3000\text{ cm}^{-1}$  to  $2800\text{ cm}^{-1}$  region, which was attributed to CH stretching (Dai and Fan 2011). From Fig. 1 it is seen that the  $\text{CH}_2$  stretching vibration can split into two absorption peaks, which are symmetric stretching vibration and antisymmetric stretching vibration. However, in the above FTIR spectra,  $\text{CH}_2$  stretching vibration appears as an absorption

peak at about  $2900\text{ cm}^{-1}$ , which is due to the effect of hydrogen bonds after the  $\text{CH}_2\text{OH}$  group became aligned with the crystal lattice during beating. This resulted in the double peaks of symmetric and antisymmetric stretching vibration tending to a single peak between those for symmetric and antisymmetric stretching vibrations. Moreover, it is clear that in Fig. 1 the FTIR spectra show the absorption peak of the intra-molecular OH stretching vibration frequency changed with different beaten time. The shift to a different frequency suggests that the absorbance of the hydrogen bond strength was changed. However, the characteristic functional groups of the samples are essentially unchanged during beating, which suggested the composition was similar, because beating is just a physico-mechanical process.

**Fig. 1.** FTIR spectra of the different beating time: (a) 5 min, (b) 15 min and (c) 25 min; spectra regions: **A:**  $3800\text{-}2800\text{ cm}^{-1}$  and **B:**  $1800\text{-}600\text{ cm}^{-1}$

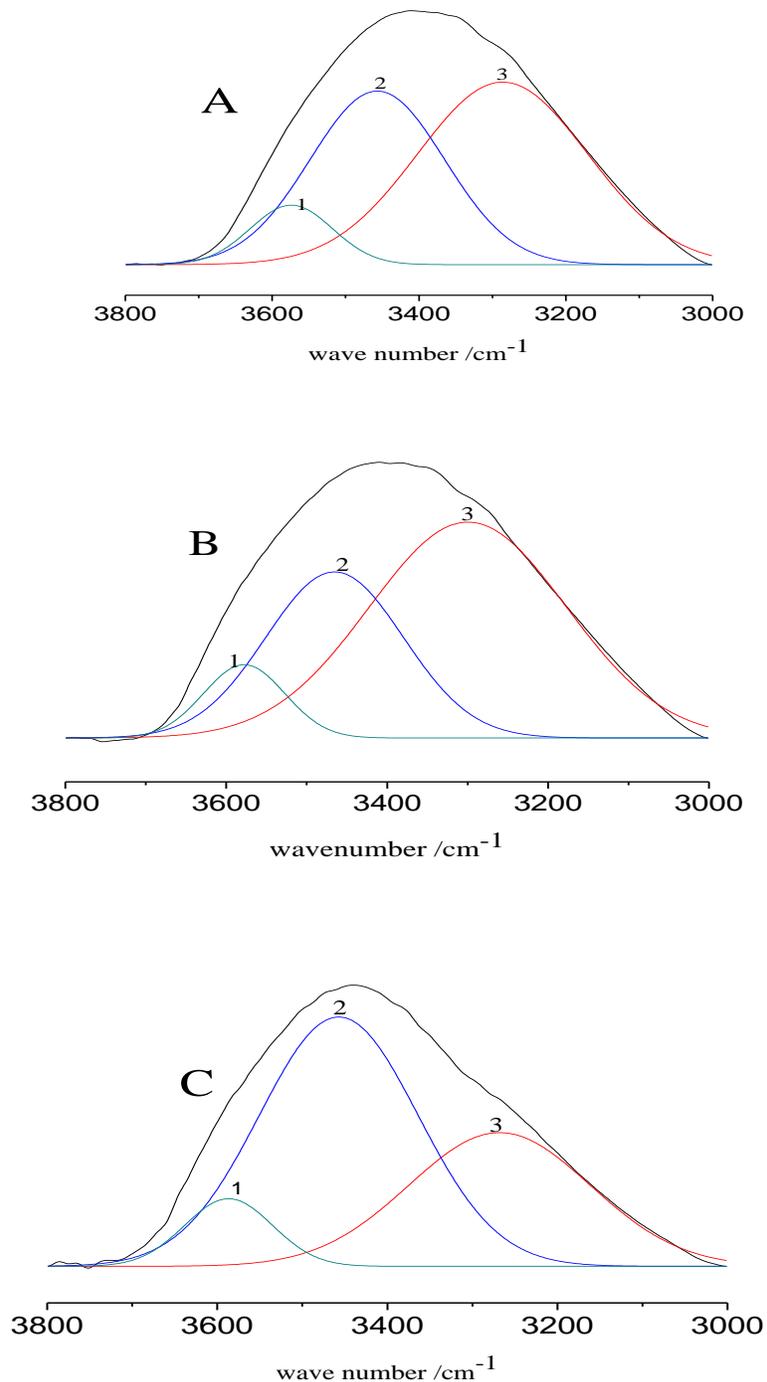

## Content of Different Hydrogen Bond Models of Eucalyptus Fibers during Beating

Despite the small changes in the shifted hydrogen bonds that were found, the details about the content of different hydrogen bond models were still unobvious. Most research has focused on functional groups stretching, whereas limited research has focused on the details about the content of different hydrogen bond models of cellulose crystallinity. Since the use of infrared spectroscopy to elucidate molecular structures, much effort has been devoted to separating the overlapping bands deriving, for example, from hydrogen bonds (Oh *et al.* 2005). Fibers join together by forming hydrogen bonds, and the strength of the sheet can be correlated to the number of inter-fiber bonds formed. The large number of polar hydroxyl groups in cellulose chains make cellulose polymer chains predestined to form hydrogen bonds within the same polymer chain strain and with other polymer chain strands. In the generally accepted structure of cellulose I, intra-molecular hydrogen bonds of the types  $O(3)H\cdots O(5)$  and  $O(2)H\cdots O(6)$  and the inter-molecular hydrogen bonds for  $O(6)H\cdots O(3')$  were studied, respectively (Schwanninger *et al.* 2004). As a result of hydroxyl groups showing different polarities, cellulose has different crystalline structures. And the cellulose fiber structural changes through various recycle periods of eucalyptus fibers were studied by FTIR (Chen *et al.* 2012).

The transformed intensity spectrum obtained from eucalyptus fibers were analyzed by using the PeakFit software's Gaussian function (Maréchal and Chanzy 2000; Oh *et al.* 2005; Popescu *et al.* 2009) to differentiate the hydrogen bond types. Generally, the curve fitting of IR spectra can enhance the apparent resolution, and amplify small differences in the IR spectra. Figure 2 shows the FTIR spectra of the hydrogen-bonded O-H stretching vibrations with the corrected baseline. Assuming that all the vibration modes follow a Gaussian distribution, mixed modes of hydrogen-bonded O-H stretching can be resolved into three bands for native cellulose.

According to Fig. 2, there was much difference among the three samples; Table 2 quantifies the results of the FTIR spectra for the amounts of hydrogen bond O-H stretching vibrations (with the baseline correction). The total content of the intra-molecular hydrogen bond  $O(2)H\cdots O(6)$  and  $O(3)H\cdots O(5)$  decreased by 17.09%, and the content of inter-molecular  $O(6)H\cdots O(3')$  increased by 11.20% when the beating time increased from 5 to 15 min. This is due to the fact that there was breakage or generation of hydrogen bonds during beating (Mohkami and Talaeipour 2011). Beating exposes the interior of the fiber, increasing surface area and allowing a greater number of inter-fiber bonds to form, strengthening the sheet. However, the total content of the intra-molecular hydrogen bond increased by 16.06% and the content of inter-molecular  $O(6)H\cdots O(3')$  decreased by 33.66% when the time was increased from 15 to 25 min, compared with the sample beaten at 5 min. Since hemicelluloses have relatively short chain lengths and the prevalence of hydrogen bonds can provide valuable linkages between two cellulose fibers, they swell greatly and absorb a good quantity of water when wet; they are also the most easily degraded compound present in wood, especially in low-yield pulping. It is likely that the beating operation affects the internal and the external surface chemical composition of the fibers, and the majority of hemicelluloses are often lost in low yield pulping with increasing beating time, which results in the decrease in the content of inter-molecular hydrogen bonding with 5 min of beating. In addition, the inter-molecular hydrogen bonding of cellulose is dominant, and it manifests itself as a force between fibers to combine the chains of cellulose, while intra-molecular hydrogen is just in

position within the auxiliary. The phenomenon is also in accordance with the regular pattern of the energy of hydrogen bonds (Struszczyk *et al.* 1986).

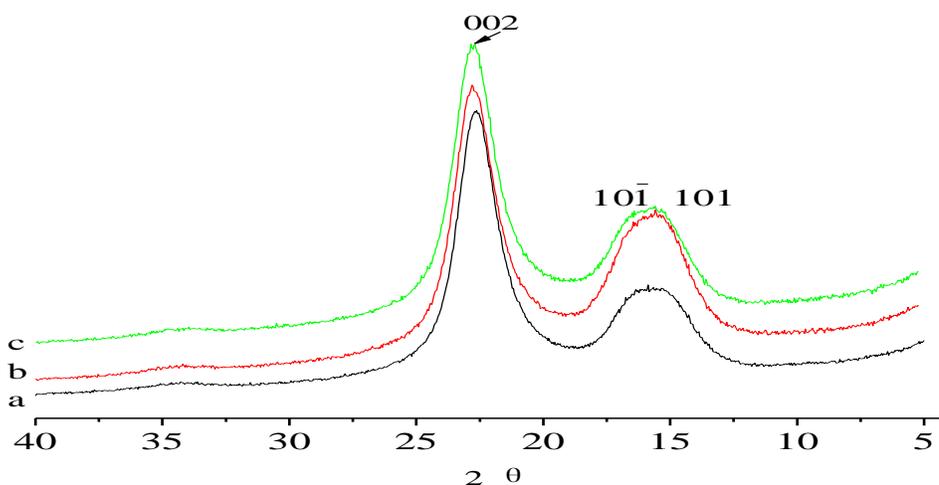

**Fig. 2.** Spectra fitting of hydrogen bond region of FTIR spectrum of eucalyptus fibers with different beating time: (A) 5 min, (B) 15 min and (C) 25 min; bonding modes: (1) intra-molecular hydrogen bond O(2)H $\cdots$ O(6); (2) intra-molecular hydrogen bond O(3)H $\cdots$ O(5); and (3) inter-molecular hydrogen bond O(6)H $\cdots$ O(3').

**Table 2.** The Content of Different Hydrogen Bond Forms Obtained by FTIR Gaussian Fitting

Beating Time (min.)	Hydrogen bond	Wave number (cm <sup>-1</sup> )	Content (%)
5	O(2)H···O(6)	3573	8.25
	O(3)H···O(5)	3456	39.33
	O(6)H···O(3')	3286	52.43
15	O(2)H···O(6)	3577	8.18
	O(3)H···O(5)	3465	31.27
	O(6)H···O(3')	3299	58.30
25	O(2)H···O(6)	3586	8.52
	O(3)H···O(5)	3457	56.70
	O(6)H···O(3')	3268	34.78

### Crystal Type of Eucalyptus Fibers by Using X-Ray Diffraction (XRD) during Beating

The XRD spectra of the eucalyptus fibers are shown in Fig. 3. As can be seen, the eucalyptus fiber peaks of X-ray diffraction curve is typical crystal diffraction of cellulose I. The results indicated that the (10 $\bar{1}$ ) and (101) faces overlap, and the diffraction angle about the (002) lattice plane differ by a small amount, which suggests that cooking process may destroy the crystalline structure of cellulose. However, the phenomenon shows that the cellulose crystal type (cellulose I) did not change.

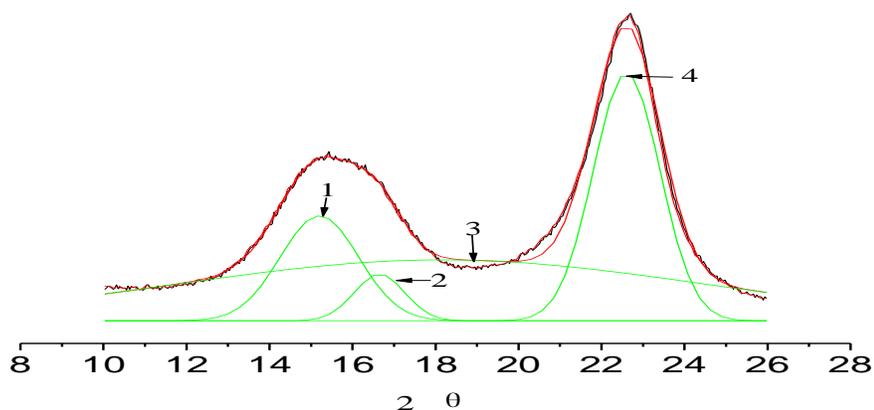

**Fig. 3.** XRD spectra of eucalyptus fibers with different beating time: (a) 5 min, (b) 15 min, and (c) 25 min.

### Microcrystalline Structure and Properties

The crystallinity of eucalyptus fibers in treated samples with different beating times were analyzed by X-ray diffraction (XRD). This method is based on the height of the diffraction peak (Segal *et al.* 1962). When the beating time was 5, 15, and 25 min, the crystallinity of the eucalyptus wood pulp samples was 80.62%, 76.30%, and 77.06%,

respectively. The information obtained shows that the relative height to the minimum can only be taken as a rough approximation of the contribution of amorphous cellulose to the cellulose diffraction spectrum (Mohkami and Talaeipour 2011). However, the precision and accuracy of diffraction peak positions resolved from the spectra by means of the residuals fitting procedure was investigated for their accuracy. In order to examine the intensities of diffraction bands and to establish the crystalline and the amorphous areas more precisely, the diffractograms were deconvoluted as shown in Fig. 4. The positions of the peaks responsible for the cellulose crystalline form I were found to be significantly different in the three eucalyptus pulps with different beating time.

After deconvolution, five bands were observed, namely: the  $14.5^\circ$  ( $2\theta$ ) reflection assigned to the (101) crystallographic plane, the  $16.5^\circ$  ( $2\theta$ ) reflection, assigned to the  $(10\bar{1})$  crystallographic plane, the  $18.0^\circ$  ( $2\theta$ ) reflection, assigned to amorphous phases, and the  $22.4^\circ$  ( $2\theta$ ) reflection, assigned to the (002) or (200) crystallographic planes of cellulose I (Colom *et al.* 2003; Marcovich *et al.* 2001). The crystallinity obtained by peak area X-ray analysis is in accordance with that found by the strength of the peak (Chen *et al.* 2004). The function which calculates mean cross sectional area ( $A$ ) is given by:  $A = L_{002} \times 1/2(L_{10\bar{1}} + L_{101})$  (where  $L_{002}$ ,  $L_{10\bar{1}}$  and  $L_{101}$  are the average width of crystal in (002),  $(10\bar{1})$ , and (101), respectively) (Hult *et al.* 2003). Crystallinity was calculated from the ratio of the area of all crystalline peaks to the total area.

**Fig. 4.** Deconvoluted XRD spectra of eucalyptus cellulose fibers: 1 (101) crystallographic plane, 2  $(10\bar{1})$  crystallographic plane, 3 amorphous phase, and 4 (002) crystallographic plane

Crucial for the analysis of the XRD data is the separation of the reflection (002) from the amorphous background and reflections of (101) and  $(10\bar{1})$ ; these peaks are separated by Gaussian deconvolution. During refining the eucalyptus fibers suffer shear and frictional forces, giving rise to internal delamination and fibrillation at the fiber surfaces. Such effects result in better conformability of the fibers. The presence of fibrils resulting from beating, along with the generation of fines and delamination between the fiber layers, such as the primary and secondary wall, imply changes in the hydrogen bonded structure, changing the crystallinity (Carvalho *et al.* 2005). In Table 3, the calculated parameters from X-ray diffractogram for the studied samples are presented.

**Table 3.** Analyses of Cellulose Super-Molecular Structure in Eucalyptus Kraft Pulps with Different Beating Time

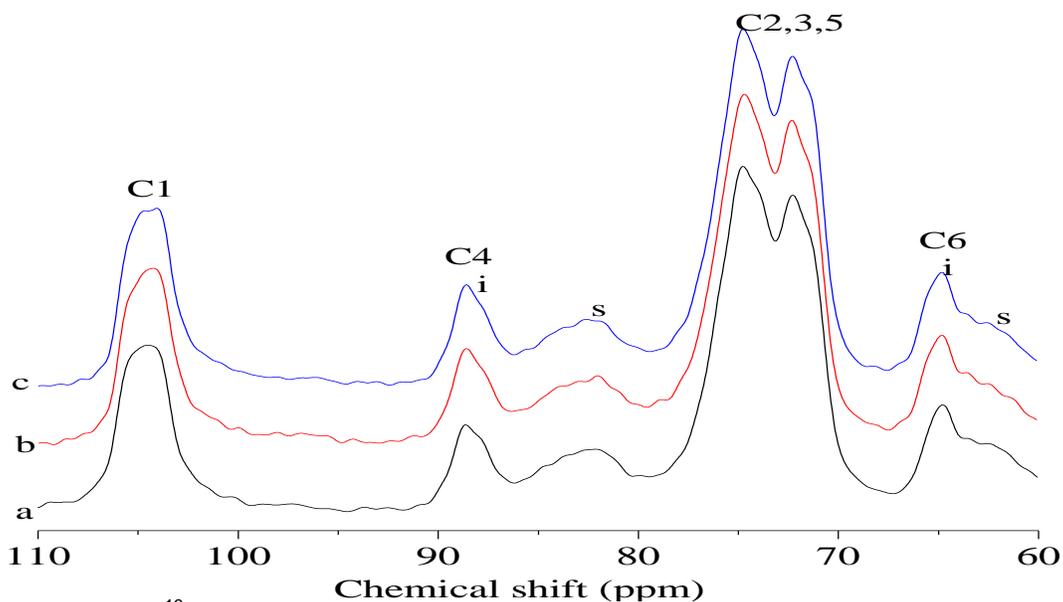

Beating time (min)	Lattice plane (nm)	Diffraction angle $2\theta$ (°)	$L_{hkl}$ (nm)	CrI (%)	A (nm <sup>2</sup> )
5	10 $\bar{1}$	15.17	5.3	76.0	31.25
	101	16.25	6.7		
	002	22.85	5.5		
15	10 $\bar{1}$	15.4	4.2	68.9	23.84
	101	16.42	7.2		
	002	22.87	5.2		
25	10 $\bar{1}$	15.23	4.6	70.2	25.93
	101	16.61	6.8		
	002	22.64	5.4		

The average width of crystal plane and the cross-sectional area of eucalyptus cellulose fibers have been analyzed (Wan *et al.* 2010). Table 3 shows the X-ray spectra of the eucalyptus fibers at different beating time. Changes in cellulose super-molecular structure of eucalyptus pulps were analyzed. The average width of diffraction peaks for (002), (10  $\bar{1}$ ), and (101) lattice planes decreased as the beating time ranged from 5 to 15 min, but when the time was extended to 25 min, the average width of lattice plane increased. The changes about the average width of crystallite in (002), (10  $\bar{1}$ ), and (101) planes exhibited the same tendency as the increase of beating time. The mean cross sectional area of the three samples changed, influencing the accessibility and homogeneity of the fibers. The present results correspond with the conclusion of native cellulose, which has been reported (Hermans and Weidinger 2003). It is likely that the increase in surface area exposes a greater number of the fibers' internal pores, allowing for more water retention initially but also causing a greater observed degree of hornification. This indicates that beating may play a role on cellulose structural changes. This also confirms the positive effect of beating in limiting the degree of cellulose hornification.

### Content of Polymorphs of the Eucalyptus Cellulose by <sup>13</sup>C NMR Spectra during Beating

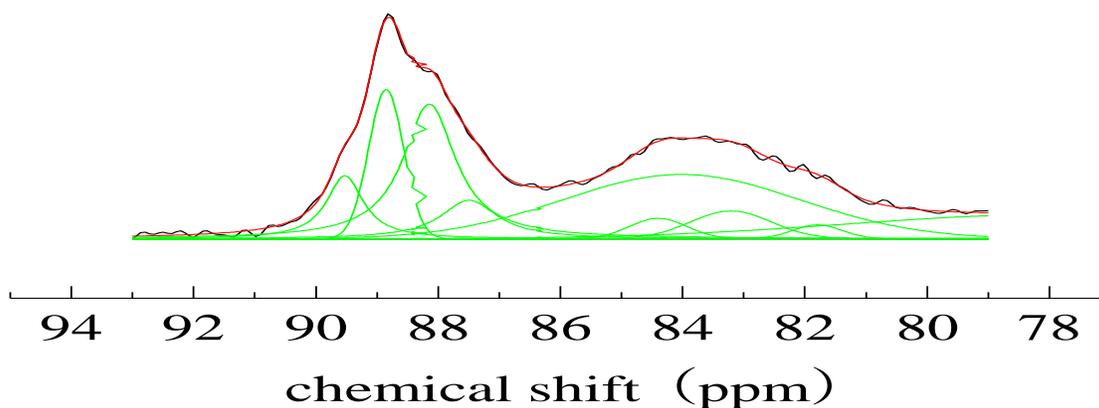

The NMR spectra of the eucalyptus pulp samples are shown in Fig. 5. The signals assigned to C4 were partly separated into two clusters, labeled *i* and *s*, which were assigned to the interiors and surfaces of the crystalline domains, respectively. Poorly resolved splitting within the cluster labeled *i* was attributed to the presence of both the I<sub>α</sub> and I<sub>β</sub> domains together with para-crystalline cellulose forms. Partly resolved splitting in the cluster labeled *s* might be associated with the non-crystalline area. Only subtle differences in spectral details can be observed between the three eucalyptus pulp samples.

Recently, a large amount of information about cellulose I<sub>α</sub> and cellulose I<sub>β</sub> has become available, and it is clear that the two forms differ in hydrogen bonding (Sugiyama *et al.* 1991); however, the precise content cannot be obtained during beating. A method for quantifying the states of order found within cellulose I has been proposed based on CP/MAS <sup>13</sup>C NMR in combination with spectral fitting (Hult 2001; Newman 2004). This approach has been used by others to assess the cellulose crystallinity (Horii *et al.* 1987; Hult *et al.* 2002).

**Fig. 5.** CP/MAS  $^{13}\text{C}$  NMR spectra of the Eucalyptus kraft pulp with different beating time: (a) 5 min, (b) 15 min, and (c) 25 min

Lorentzian and Gaussian functions were used to perform the deconvolution of the C4 peaks. A combination of Lorentzian and Gaussian functions was used to fit the C4 region (80 to 92 ppm) with seven peaks in that range (Wan 2010; Chen 2010; Newman 2004). The peak assigned to more ordered cellulose structures includes those peaks previously assigned to the  $I_\alpha$ ,  $I_\beta$ , and para-crystalline cellulose components (see Fig. 6).

**Fig. 6.** Lorentzian and Gaussian line shape-fitting of the C-4 spectral region of eucalyptus fibers

The results of the spectral fitting for the cellulose C4 region of the  $^{13}\text{C}$  NMR spectra of the pulps with different beating times are shown in Fig. 6 and Table 4. It is apparent that the different cellulose polymorphs are usually analyzed on the basis of the form of the C4 signal. During the beating process the content of different cellulose polymorphs were obtained. There were little changes in the content of cellulose  $I_\alpha$  and cellulose  $I_\beta$ , but the content of the cellulose  $I_\beta$  in the three samples was observed to be substantially higher than cellulose  $I_\alpha$ .

**Table 4.** Results of Spectral Fitting for the C4 Region of CP/MAS  $^{13}\text{C}$  NMR Spectrum, Cellulose  $\text{I}_\alpha$ , Cellulose  $\text{I}_{\alpha+\beta}$ , Cellulose  $\text{I}_\beta$ , CrI with Different Beating Time

Beating time (min.)	5	15	25
Cellulose $\text{I}_\alpha$ (%) 88.8 ppm	4.18	4.01	4.23
Cellulose $\text{I}_{\alpha+\beta}$ (%) 88.7 ppm	1.4	3.4	2.8
Cellulose $\text{I}_\beta$ (%) 86.7 ppm	34.8	29.5	33.2
Para-crystalline cellulose(%) 87.9 ppm	19.2	18.3	20.1
CrI (%)	61	57	60

Results are in complete agreement with  $\text{I}_\alpha$  cellulose which has been reported to be the dominant polymorph in bacterial and algal celluloses, while  $\text{I}_\beta$  cellulose is predominant in higher plants such as cotton and wood (Sun *et al.* 2004). Temperature is well controlled, and it is the most important factor among the parameters which seem to influence the transformation between  $\text{I}_\alpha$  and  $\text{I}_\beta$  (Debzi *et al.* 1991; Popescu *et al.* 2007). It could be expected that para-crystalline cellulose was converted into the more stable cellulose  $\text{I}_\beta$ , not the cellulose  $\text{I}_\alpha$ . And the replacement of cellulose-water interactions by cellulose-cellulose interactions may affect the cellulose structure and dynamics of the cellulose hydrogen bonds at the fibril surfaces, resulting in the changes in the content of the polymorphs of the eucalyptus cellulose. However, this may be a very inconspicuous change. The crystallinity of the cellulose decreased when the beating time ranged from 5 to 15 min. This demonstrates that the special structure of PFI refining plate induces an “external effect” on the fibers (Liu *et al.* 2002), and this hardens the fiber surfaces and the partly activates the cellulose. However, the crystallinity increased slowly when the beating ranged from 15 to 25 min. The reason was that more hydroxyl groups are fractionated out with further beating (Bhardwaj *et al.* 2007), which results in the adsorption of free water by fiber. Subsequently, during the drying or paper, water evaporates from the voids of cell walls, leading to the irreversible collapse of the cell wall. Hence, the crystallinity increased. As can be seen, the changes of the crystallinity during beating obtained by  $^{13}\text{C}$  NMR were in full agreement with the results obtained by X-ray diffraction. It can be concluded that the pulp’s ability to form fiber-fiber hydrogen bonds is regenerated to some extent during beating.

### Changes of Crystal Size of Eucalyptus Fibers during Beating

The average lateral fibril and lateral fibril aggregate dimensions are calculated from quantitative spectra of pure cellulose isolated from the kraft pulps (Hult *et al.* 2000; Wickholm *et al.* 1998).

In Table 5, it is apparent that the average fibril sizes and fibril aggregate sizes are also given for the three samples; the average fibril size was relatively constant between 5.18 and 4.6 nm for the three samples, which exhibited no major differences. However, the cellulose fibril size calculated by the NMR method was lower than that obtained by X-ray Diffraction. For example, when the beating time was 5 min, the CP/MAS  $^{13}\text{C}$  NMR estimates gave a lateral fibril dimension of 5.18 nm, but the average width of crystallites

in 002 (lateral fibril dimension) was 5.5 nm. The probable reason for the difference was that only material within the crystallites appears as crystalline in NMR spectra; therefore the NMR crystallite size depends on crystalline perfection (Maunu *et al.* 2000). However, the fibrils aggregate size ranges from 22.2 nm to 27.8 nm. The only significant difference is the change of the fibrils aggregate dimensions.

**Table 5.** The Results of Spectral Fitting for the C4 Region of CP/MAS  $^{13}\text{C}$  NMR Spectrum, Accessible Fibril Surfaces, Inaccessible Fibril Surfaces, Lateral Fibril Dimension, and Fibrils Aggregate Size with Different Beating Times

Beating time (min)	5	15	25
Accessible fibril surfaces (%) 84.09 ppm , 81.43 ppm	9	10	8
Inaccessible fibril surfaces (%) 83.18 ppm	30	33	32
Lateral fibrils size (nm)	5.18	4.6	5.0
Lateral fibrils aggregate size (nm)	24.7	22.2	27.8

As a result of beating, the fiber wall is fractured and some of the surface material is removed, exposing more hydroxyl groups. Thus, beating increases the interaction between fiber and water, and it results in more microfibrils (Nishiyama *et al.* 2002). This allows for increased swelling of the fiber during beating, and it can lead to further fibril aggregation during papermaking (Hult *et al.* 2001).

## CONCLUSIONS

This work presents an attempt to explain the influence of beating time on the content of hydrogen bonds corresponding to different models. Also, it was shown that beating affects the crystallinity of eucalyptus pulp fibers, as well as the different cellulose polymorphs. Pulp with different beating time differed greatly in structure. By increasing the beating time, both the content of different hydrogen bonds and the crystallinity were affected. Accordingly, greater changes occurred in the average fibril aggregate size and cellulose crystalline types. Cellulose crystallinity decreased and then increased with an increase in beating time. The average fibril sizes and fibril aggregate sizes of unbleached eucalyptus fibers increased with the increase in crystallinity. In confronting the characteristics of fibers recreated during beating, it appears that the mechanical action of beating can modify fiber ultra-structural integrity in a way that should potentially improve final paper properties and does not cause extreme damage in the fiber.
