Natural Fiber-based Composites with High Hydrophobic, Magnetic, and EMI Shielding Properties *via* Iron Oxide *In Situ* Synthesis and Copper Film Deposition

Quanliang Wang,[a] Jie Tang,[b] Shengling Xiao,[a,*] Min Wang,[c,*] and Sheldon Q. Shi [d]

A sandwich-structured natural fiber-based magnetic composite, without the use of a binder, was developed in this study. It was fabricated *via in situ* synthesis, densification, and magnetron sputtering processes. The chemical composition, crystal structure, microstructure, and thermal stability were characterized *via* X-ray photoelectron spectroscopy, energy-dispersive spectroscopy, X-ray diffraction, scanning electron microscope, and thermogravimetric analysis. The hydrophobic, magnetic, and electromagnetic interference shielding properties were investigated by measuring the static water contact angle, the magnetic hysteresis loops, and the shielding effectiveness. The resulted composites exhibited a unique inner structure with a larger iron oxide size and content (492 nm and 26.1 wt%) on the interlayer surface in comparison to the core layer (135 nm and 18.7 wt%). The magnetic response can be controlled by the loaded iron oxide content and the copper film deposition. Sputtering copper film changed the surface free energy, and created rough micro-/nanostructures, which yielded a highly hydrophobic nature (133° in water contact angle), and approximately 99.2% of the electromagnetic energy was shielded by the 0.8 mm thick composite.

INTRODUCTION

The rational growth and array design of nanostructures on polymeric matrices are of great importance in terms of constructing multifunctional materials with high performance. Considering the merits of different materials, the design of functional composite materials with excellent constructions, *e.g.*, sandwich structure, are emerging as an effective way to solve the paradox between different properties, such as high breakdown strength and enhanced permittivity (Wang *et al.* 2017). A sandwich-structured composite, which is composed of an electrically conductive layer and a carbonaceous or polymeric substrate, has potential advantage as an electromagnetic interference (EMI) shielding media by combining the characteristics of conductivity and stable interlayers (Liu *et al.* 2014). To date, sandwich-structured composites comprising of carbonaceous materials, transition-metal oxides, conducting polymers, *etc.* have been widely designed ($MnO_2/Mn/MnO_2$ (Li *et al.* 2012), Graphene-Fe_3O_4@Carbon (Zhao *et al.* 2015), Co_3O_4@Carbon Fiber@Co_3O_4 (Shi *et al.* 2018), ZnO/ZnS/Au (Liu *et al.* 2015c), C/Ge/Graphene (Li *et al.* 2013), Nafion/PtRu@SiO_2/Nafion (Wu *et al.* 2013), Pt@ZSM-5 nanosheets (Liu *et al.* 2019), C@Si@C nanotube array (Liu *et al.* 2015a), PANI/

graphene/PANI (Tong *et al.* 2014), PVDF@BT/PVDF/BT@PVDF (Wang *et al.* 2017), $NaYF_4$@$NaYF_4$: Er^{3+}/Yb^{3+}@$NaYF_4$ (Zhang *et al.* 2018), and PVDF/PMIA/PVDF (Zhai *et al.* 2014), $PVDF/BaSrTO_3/TiO_2$ (Hu *et al.* 2013)) and applied in supercapacitors (Liu *et al.* 2015b; Choi *et al.* 2016), lithium batteries (Song *et al.* 2014a; He *et al.* 2015), hydrogen storage (Feng *et al.* 2016; Han *et al.* 2017), biological detection (Meher and Rao 2013), photocatalysts (Tian *et al.* 2014), surface-enhanced Raman scattering (Liu *et al.* 2014), and anisotropic conductive films (Yang *et al.* 2019) to improve device performance. However, most of these structural materials are confined to nanocomposites or composite membrane materials. For practical applications, these sandwich-structured nanocomposites have to be further processed by mixing in order to form the macroscopic composites. In addition, these materials are usually subjected to high temperature treatment, and thus they have to rely on additional binders during further processing.

      The rapid development of technology along with various electronic devices, *e.g.*, communication facilities, wireless networks, and portable digital hardware, has drawn the most concern in terms of electromagnetic pollution. Electromagnetic radiation not only interferes with the operation of electronic devices, but it also causes serious health risks in humans (Song *et al.* 2014b). Multifunctional materials, such as EMI shielding products, play a more important role in today's society in terms of blocking and attenuating unexpected electromagnetic irradiations (Munaweera *et al.* 2014; Gan *et al.* 2017b). In recent years, searching for electromagnetic attenuation materials has become a hot topic. Incorporating conductive fillers into polymeric matrices is considered to be an effective way to fabricate EMI shielding materials, owing to their easy processing and adjustable shielding performances (Wang *et al.* 2019a). Most of the research focuses on introducing various carbon materials, *e.g.*, graphene, carbon nanotube, carbon nanofiber, and carbon black (Li *et al.* 2006; Al-Saleh *et al.* 2013; Lee *et al.* 2017); metal oxides, *e.g.*, Fe_3O_4, MnO_2, and CrO_2 (Menon *et al.* 2019; Wang *et al.* 2019a); and noble metals, *e.g.*, Au nanoparticles and Ag nanowires (Fang *et al.* 2016; Sun *et al.* 2018) into polymeric matrices, such as polyurethane (PU) and polyaniline (PANI) (Thomassin *et al.* 2013; Shen *et al.* 2016), for high-efficient EMI shielding. These composites comprising of conductive fillers and polymers can achieve the desired EMI shielding performance. However, there still remains some challenges, namely the high cost of electrically conductive fillers, *e.g.*, the widely used graphene and PANI, and the environmental impacts due to petroleum-derived polymer substrates.

      Natural fibers for functionalized composites have attracted an increasing amount of attention in the applied fields of biomedicine, electronics, and energy, due to their low cost, lightweight nature, high chemical stability, as well as being environmentally friendly (Gan *et al.* 2017a). In addition, biomass-derived fibers, *e.g.*, wood fibers, usually have a hollow cell wall structure, which can serve as an efficient substrate for loading conductive active materials in order to improve EMI shielding properties. The existing method for fabricating EMI shielding natural fiber composites is to first introduce electrically conductive materials, such as iron oxide (Ding *et al.* 2015; Xia *et al.* 2016b), carbon nanotubes (Tzounis *et al.* 2014), or powdered activated carbon (Xia *et al.* 2015), into the natural fibers, and then to use these treated fibers to fabricate the final EMI shielding composites. However, owing to the limited void space in fiber lumina for the filler loading, the EMI shielding function of natural fiber composites is restricted. Moreover, these composites are fabricated with the assistance of additional adhesives, such as phenol formaldehyde and urea formaldehyde. Coating a thin metal film on the surface of the composite can also achieve the EMI shielding. Especially for natural fiber materials, their hydrophilic defects

can be solved by depositing a hydrophobic metallic film. Compared to other coating substances, copper can be used to form the thin films needed for EMI shielding applications while providing oxidation resistance and acceptable costs (Wu *et al.* 2018). Meanwhile, magnetron sputtering provides a convenient copper film coating route with a high deposition rate (Kim *et al.* 2018; Wang *et al.* 2019b). Researchers have reported that magnetron sputtering a thin copper film onto the surface of natural fiber composites for EMI shielding demonstrated good hydrophobicity from the resulting composite (Xia *et al.* 2016a; Wang *et al.* 2019b). However, the heterogeneous interfacial bonding between the biomass substrates and the metallic coatings becomes a challenge when the thin metallic films are directly deposited onto the cellulosic fiber surfaces.

In this work, a novel sandwich-structured natural fiber composite was developed. The magnetic interlayer is comprised of natural fibers and iron oxide particles, while the outer layers are a thin copper film. The iron oxide compounds were first *in situ* synthesized into a porous natural fiber matrix. The moist fiber matrix/iron oxide complex was then densified *via* hot pressing. Finally, the densified magnetized fiber matrix was sandwiched between thin copper films *via* magnetron sputtering. The morphology and compositions were characterized *via* scanning electron microscopy (SEM), energy-dispersive spectroscopy (EDS), X-ray diffraction (XRD), Fourier transform infrared spectroscopy (FTIR), and X-ray photoelectron spectroscopy (XPS). The hydrophobicity, thermal stability, magnetic function, and EMI shielding properties were investigated *via* thermogravimetric analysis (TGA), static water contact angle, magnetic hysteresis loop, and EMI shielding effectiveness, respectively.

EXPERIMENTAL

Materials

The chemi-thermomechanical pulp fibers from poplar wood were fabricated in the laboratory by reference to our previous work (Wang *et al.* 2018). All of the following chemicals were purchased from the Sinopharm Chemical Reagent Company (Beijing, China): iron trichloride hexahydrate ($FeCl_3 \cdot 6H_2O$ greater than 98.0% purity), iron dichloride tetrahydrate ($FeCl_2 \cdot 4H_2O$, greater than 98.0% purity), hydrochloric acid (HCl 38.0%), and ammonium hydroxide solution ($NH_3 \cdot H_2O$ 28.0%).

In situ synthesis and densified treatment for the composite interlayer

The *in situ* synthesis of the iron oxide compounds was performed on a natural fiber matrix (0.29 g cm^{-3}), which was made of pulp fibers *via* a mild molding process. A 40 mm × 40 mm × 3.8 mm fiber matrix was impregnated in an acidic solution containing $FeCl_2$ and $FeCl_3$ at room temperature for 3 h. The mixed solutions (60 mL) were prepared with different iron ion contents (3.75E-3 mol Fe^{3+}/1.875E-3 mol Fe^{2+}, 7.5E-3 mol Fe^{3+}/3.75E-3 mol Fe^{2+}, and 1.5E-2 mol Fe^{3+}/7.5E-3 mol Fe^{2+}). Subsequently, the iron ion solutions (containing the fiber mat) were heated at 80 °C in a water bath, and the pH value of the reaction solution was adjusted to 9.0 by adding ammonium hydroxide, which was maintained for 1 h while stirring. According to previous reports (Pang *et al.* 2010; Chin *et al.* 2014), the iron oxide compounds were *in situ* synthesized in the fiber matrix.

The densification of the natural fiber/iron oxide complexes was performed at a high temperature without using any binders. After an ultrasonic wash in distilled water, the magnetized fiber matrices (with a moisture content of *ca.* 50%) were hot pressed at 170 °C

and 4 MPa for 20 min. Then the densified magnetized fiber matrices (DM-FM) were obtained. The DM-FM composites (*i.e.*, the interlayer used for the magnetic composites) with an iron oxide loading content from low to high were coded as DM-FM-a, DM-FM-b, and DM-FM-c, respectively. Note that the iron oxide particles and the natural fiber matrices were also separately compressed at 170 °C, and the obtained hot-pressed iron oxide and pristine fiber sheet were used as the control groups.

Thin copper film magnetron sputtering for the sandwich structure

The sandwich structure was constructed by depositing a thin copper film on the surface of the DM-FMs to instill a highly hydrophobic nature and increase EMI shielding performance. A DLZ-01 plasma-based ion injector (Harbin Institute of Technology, Harbin, China) was used to deposit the thin copper film using a high-purity copper target (99.9%). A copper target current of 300 mA was applied during the deposition process. The sputtering vacuum pressure was adjusted to approximately 0.5 Pa using argon gas with a flux of 30 sccm. Prior to the sputtering, each sample was cut to 20 mm × 20 mm. The processing time was set for 1.0 h. The sputtered DM-FM-c specimen was coded as SDM-FM-c.

Methods

The scanning electron microscope (SEM) observations were performed with FEI Quanta-200 microscopy (Hillsboro, OR, USA) equipped with an energy-dispersive spectroscopy (EDS) detector for element analysis. To determine the particle size distributions, *ca.* 200 metal grains were measured in the obtained SEM images with a $10000\times$ magnification for each sample. The X-ray photoelectron spectroscope (XPS) analysis was carried out with a Thermo Escalab 250Xi spectrometer (Waltham, MA, USA) equipped with a dual X-ray source using Al-Kα, where the deconvolution of the overlapping peaks was conducted with a mixed Gauss-Lorentz fitting software program (XPSPEAK41, Thermo Fisher Scientific Company, Waltham, MA, USA). The X-ray diffraction (XRD) spectra were recorded with a Rigaku D/max 2200 instrument (Tokyo, Japan) at a scan rate 8 °min^{-1} and a scan range (2θ) from 5° to 80°. The crystallinity index was calculated using the Segal method (Fei *et al.* 2017). The Fourier transform infrared (FTIR) spectra were recorded with a PerkinElmer Frontier instrument (Waltham, MA, USA) in the range from 4000 cm^{-1} to 400 cm^{-1} with a resolution of 4 cm^{-1}. The thermal properties, in terms of thermogravimetric (TG) analysis and its derivative thermogravimetric (DTG) analysis were studied with a TA SDT Q600 simultaneous thermal analyzer (TA Instruments, New Castle, DE) by heating the samples from room temperature to 900 °C with a heating rate of 20 °C/min under a nitrogen flow of 100 mL/min. The ash content was determined with a YX- HF ash monitor (Xuyu Technology Co., Ltd, Tianjin, China) at 900 °C for 60 min, according to standard GB/T 742 (2008). Iron oxide only undergoes phase transformation with minimal weight loss under the pyrolysis conditions with a temperature range of 200 °C to 900 °C (Pan *et al.* 2011). Thus, the iron oxide loading content can be evaluated by calculating the residual ash content, with the exception of the natural fibers. The thickness of the thin copper film was measured using a back scattered electron imaging technique with a SEM by observing the sample cross-sections (Zhu *et al.* 2008).

The hydrophobic properties of the samples were characterized by the static water contact angle at a contact time of 1 min, using an OCA20 contact angle analyzer (Data Physics Co., Regensburg, Germany) at ambient temperature, and five measurements at

different places were averaged as the water contact angle value. The magnetic properties were measured on a LakeShore 7404 vibrating sample magnetometer (VSM) (Lake Shore Cyrotronics, Westerville, OH) at room temperature with an applied field of -15 kOe to 20 kOe. The EMI shielding effectiveness (SE) measurements were conducted with an Agilent N5244A PNA-X Network Analyzer (Santa Clara, CA, USA). The scattering parameters (S_{11} and S_{21}) in the frequency range of 8.2 GHz to 12.4 GHz were recorded. The total EMI SE (SE_{total}), absorption shielding (SE_A), and reflection shielding (SE_R) were obtained using Eq. 1, Eq 2., and Eq 3. The SE_{total} can be expressed as Eq. 1,

$$SE_{total} \text{ (dB)} = 10\lg (P_1/P_2) = 20\lg (E_1/E_2) = SE_A + SE_R + SE_M \qquad (1)$$

where P_1 (E_1) and P_2 (E_2) are the power (electric field) of incident and the transmitted electromagnetic wave, respectively (Wan and Li 2016). SE_A, SE_R, and SE_M are the shielding effectiveness due to absorption, reflection, and multiple internal reflection, respectively (Wan and Li 2016). Usually, the SE_M can be ignored when the SE_{total} is higher than 10 dB (Bora *et al.* 2016). In addition, SE_R and SE_A can be described by Eqs. 2 and 3,

$$SE_R = -10\lg (1 - R) \qquad (2)$$

$$SE_A = -10\lg (T/(1 - R)) \qquad (3)$$

where the reflected power (R) and transmitted power (T) can be derived from the scattering parameters (S_{ij} denotes the power transmitted from port i to port j), *viz.*, $R = |S_{11}|^2 = |S_{22}|^2$, $T = |S_{12}|^2 = |S_{21}|^2$ (Bi *et al.* 2017). The absorbed power (A) is calculated from the reflected and transmitted power, *viz.*, $A = 1 - R - T$. There are several factors that can affect the EMI shielding effectiveness, *e.g.*, conductivity, complex permeability, and complex permittivity (Bora *et al*. 2016).

RESULTS AND DISCUSSION

Preparation Process of Natural Fiber-Based Magnetic Composites

The sandwich-structured magnetic composites were developed *via* a three-step procedure including *in situ* synthesis of iron oxide compounds, densification of the fiber/iron oxide complex, and copper film magnetron sputtering (as shown in Fig. 1). The densified composite interlayer was sandwiched between thin copper films to form the final magnetic composites.

As shown in Fig. 1, the composite interlayers were fabricated from a porous natural fiber mat. During the *in situ* synthesis process, the ammonia penetrated the fiber mat surface into its interior, which formed an ammonia concentration gradient. Thus, the iron oxide was unevenly grown and distributed in the fiber mat. In order to improve the interlayer strength, the fiber/iron oxide complex (*ca.* 50% moisture content) was densified *via* hot pressing, which could also enable the immobilization of the iron oxide compounds within the fiber mat. It is worth noting that the *in situ* method can allow for a higher iron oxide loading content due to the larger pore spaces in the fiber mat.

The outer layers of the composites were constructed *via* magnetron sputtering copper film on the surfaces. Owing to the gradient iron oxide distribution, the nano-sized iron oxide particles were beneficial to the internal bonding strength, and the formed surface metallic texture could also be conducive to the copper film deposition.
Fig. 1. Schematic to illustrate the fabrication processes for the natural fiber-based magnetic composites

Characterizations *via* SEM, EDS, XRD, FTIR, and XPS

The microstructures and element components of the magnetic composites were investigated *via* SEM observations and EDS analysis, respectively (as shown in Fig. 2). As shown in Fig. 2a and Fig. 2e, the pristine fiber sheet showed a smooth surface without any heterogeneous particles. These fibers were well intertwined and bonded. Figures 2b, 2f, and 2m exhibit the inner morphology of the magnetic composites, where the iron oxide nanoparticles, with uniform sizes (*ca.* 135 nm in diameter), were densely bonded and arrayed onto the surface of the fibers. The porous fiber mat allowed for the full penetration of the iron ions into the inter-fiber pores, which facilitated the formation of iron oxide nanoparticles *in situ* within the fiber mat. Figures 2c, 2g, and 2n show the interlayer surface of the magnetic composites, where the larger-sized iron oxide particles (492 nm in diameter) were formed on the surface. This could be attributed to the inhomogeneous growth and array of iron oxide compounds in the natural fiber matrix during the *in situ* synthesis and hot pressing processes; thus, a hierarchical structure was constructed in the interlayer. Notably, the enrichment of iron oxide not only serves as a protective layer for the cellulosic substrate, but also provides enough metallic sites for structural interlocking with the sputtered thin copper film. The rough metallic surface comprising of oxide particles and micro-sized fiber network provided a platform for copper atoms penetration and the corresponding film attachment. Figures 2d, 2h, and 2o show the outer layer of the magnetic composites. As expected, the nano-sized spherical copper grains (497 nm in diameter) were densely deposited on the iron oxide loaded fiber surface, and a highly metallic texture was formed on the surface of the composites.
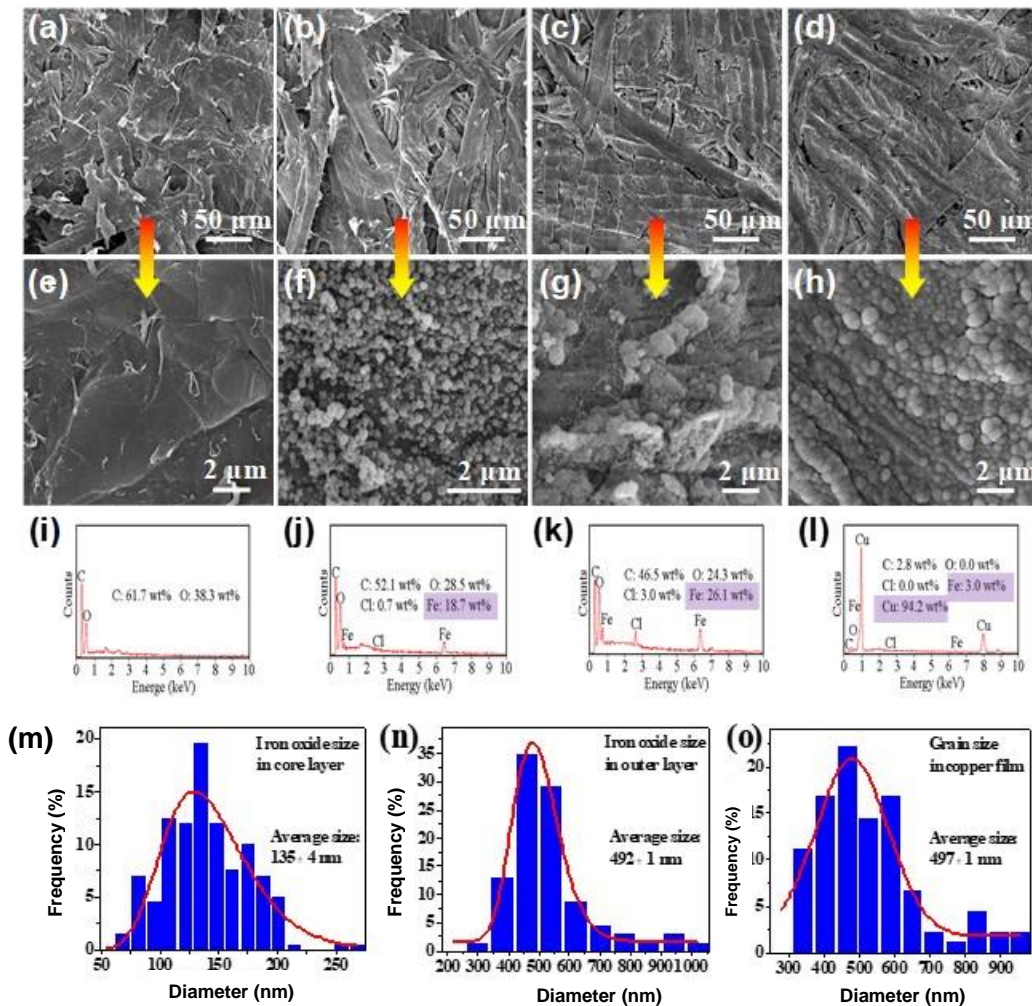

Fig. 2. SEM images of the core layers (a: pristine fiber sheet; b: DM-FM-c) and the outer layers (c: DM-FM-c; d: SDM-FM-c), and their corresponding high-resolution SEM images are presented in (e), (f), (g), and (h), respectively. The EDS spectra of the core layers (i: pristine fiber sheet; j: DM-FM-c) and the outer layers (k: DM-FM-c; l: SDM-FM-c). The statistical grain size distributions of iron oxide are shown (a: core layer of DM-FM-c; b outer layer of DM-FM-c) and thin copper film (c: outer layer of SDM-FM-c).

The pristine fiber sheet was primarily composed of C and O elements, determined by the EDS analysis (Fig. 2i). After the *in situ* synthesis of the iron oxide compounds, strong Fe peaks appeared at 0.73 keV and 6.41 keV, (Fig. 2j), which indicated the successful introduction of iron oxide into the fiber mat, which also resulted in the O/C value decreasing from 0.62 to 0.55. Importantly, from the core layer to the outer layer of the magnetic composites (as shown in Fig. 2j and Fig. 2k), the Fe content increased from 18.7 wt% to 26.1 wt%, and the O/C value decreased from 0.55 to 0.52, which demonstrated the gradient distribution of the iron oxide compounds in the interlayer, and was in good agreement with the SEM observation results. Thus, the hierarchical structure of the composite interlayer was further demonstrated. After sputtering the thin copper film, strong copper peaks appeared at 0.96 keV and 7.96 keV (Fig. 2l), and the copper content was as high as 94.2 wt%. Except for the pristine fiber sheet, a weak Cl peak was detected in other

bioresources.com

samples, which was owed to the hydrochloric treatment that was part of the synthesis process.

The crystal structures of the magnetic composites were analyzed *via* XRD (Fig. 3). The pristine fiber sheet revealed a typical cellulose I crystal structure with a main diffraction peak at 22.5° (002 lattice plane) and a shoulder in the region from 14° to 17° (Mmed *et al.* 2010; Sonia and Dasan 2013). The hot-pressed iron oxide (170 °C) exhibited six peaks at 30.3°, 35.7°, 43.0°, 53.8°, 57.2°, and 62.8°, corresponding to the (220), (311), (400), (422), (511), and (440) planes of the γ-Fe_2O_3 crystal structure (JCPDS card no. 39-1246), respectively (Pan *et al.* 2011). The XRD pattern of the magnetic composites verified the co-existence of γ-Fe_2O_3 and cellulose I crystals. The crystallinity index decreased from 68.4% (the pristine fiber sheet) to 41.3% (the magnetic composites), which could be related to the hydrochloric acid treatment during the synthesis process. Three peaks at 43.4°, 50.5°, and 74.3°, which corresponded to the (111), (200) and (220) planes of copper (JCPDS card no. 04-0836), were observed for the sputtered composites, which indicated that the thin copper film was deposited onto the composite interlayer surface (Wiatrowski *et al.* 2011).

Fig. 3. The XRD patterns of magnetic composites (The bottom line is the standard JCPDS card No. 39-1346 for γ-Fe_2O_3)

The chemical compositions of the magnetic composites were analyzed *via* FTIR and XPS (Fig. 4). As shown in Fig. 4a, the absorption band at 579 cm^{-1} was assigned to the Fe-O vibrations in the iron oxide compounds (Qian *et al.* 2009). After the insertion of iron oxide, there was an enhanced absorption peak centered at 579 cm^{-1} found in the magnetic composites. Moreover, the decreased absorption intensities at approximately 1034 cm^{-1}, 1373 cm^{-1}, and 1425 cm^{-1} corresponded to the C-O, C-H, and CH_2 groups of cellulose, respectively (Belouadah *et al.* 2015). This also indicated a transformation of the cellulosic material into a metallic texture during the synthesis and sputtering processes. The absorption bands at approximately 1638 cm^{-1} and 3430 cm^{-1} were assigned to the vibrations of water molecules (Ramandi *et al.* 2017). The absorption peaks at 1732 cm^{-1} and 2885 cm^{-1}, *i.e.*, the characteristics of unconjugated CO groups and symmetrical CH groups in hemicelluloses, showed a decreased intensity, which indicated that the hemicelluloses were partly degraded during the *in situ* process (Mulinari *et al.* 2016).
Fig. 4. The FTIR spectra (a) and high-resolution XPS spectra of (b) Fe 2p, (c) O 1s, and (d) Cu 2p$_{3/2}$ for magnetic composites.

To further clarify the compositions of the iron oxide compounds and copper film, the high-resolution XPS spectra of Fe 2p, O 1s, and Cu 2p$_{3/2}$ were measured (Figs. 4b, 4c, and 4d). As shown in Fig. 4b, two peaks at 710.8 eV and 724.5 eV were assigned to the Fe 2p$_{3/2}$ and Fe 2p$_{1/2}$ electron binding energies, respectively. Two satellite peaks were observed on both sides of the Fe 2p$_{1/2}$ peak. These satellite structures are characteristic for Fe^{3+} and indicate the absence of Fe^{2+} (Zhang *et al.* 2011; Wu and Wang 2014). Interestingly, a new split peak appeared at 530.1 eV (Fig. 4c), which was assigned to the oxygen atom that was bound to the iron atoms (Fe-O) (Li *et al.* 2016). These results confirmed the presence of γ-Fe$_2$O$_3$ in the magnetic composites.

The peak fitting results of Cu 2p$_{3/2}$ are shown in Fig. 4d to study the copper states in the film. The main Cu2p$_{3/2}$ peak at 932.7eV represented the Cu^0 in Cu metal, while the minor Cu 2p$_{3/2}$ peak at 934.6eV (along with two satellite peaks at 941.8 eV and 944.1 eV) were assigned to the Cu^{2+} state in CuO, as reported by Meng *et al.* (2016), Nourbakhsh *et al.* (2016), and Liu *et al.* (2017). Compared with the Cu^{2+} content (38%), a higher Cu^0 content (62%) was obtained through calculation of the peak area, which indicated that most of the surface copper atoms are metallic.

Hydrophobicity, Thermal Stability, Magnetic Responsivity, and EMI Shielding Performance

The sample dimensions and iron oxide content of the natural fiber-based magnetic composites are listed in Table 1. The fiber mat showed a reduction in thickness of approximately 73%, and correspondingly showed a 3.8-fold increase in density after a hot-pressing treatment. This resulted in the magnetic composites having a thickness of *ca.* 0.8 mm. The iron oxide loading content ranged from 4.0% to 11.2% by increasing the iron ion

2015). It was noted that the magnetic composites showed a lower weight loss (61.7%) compared to the pristine fiber sheet (84.8%) at temperature ranges of 180 °C to 450 °C. The magnetic composites also remained at a higher residual ash weight than the pristine fiber sheet at 880 °C. Interestingly, a DTG peak emerged at ca. 610 °C for the magnetic composites, which could be attributed to the phase transition from γ-Fe_2O_3 into α-Fe_2O_3 (Pan *et al.* 2011; Piraman *et al.* 2016).

Fig. 6. TG and DTG spectra of the magnetic composites

The magnetic responsivity was evaluated by measuring the magnetic hysteresis loops (Fig. 7a). As shown in Fig. 7a, except for the pristine fiber sheet, all the magnetic composites showed that the coercivity and remanence were close to zero in the magnetization curves, which definitely demonstrated ferromagnetic properties (Ramandi *et al.* 2017). The saturation magnetization (M_s) was increased, from 1.5 to 4.4 emu/g, with the iron oxide loading content increasing from 4.0% to 11.2% (as shown in Table 1), which indicated that a stronger magnetic response could be achieved by increasing the iron oxide loading amount. Interestingly, the saturation magnetization was further increased to 5.7 emu/g after sputtering copper film onto the fiber/iron oxide complex, which could be attributed to the increased specimen thickness after coating and the changes in the ferromagnet lattice constant after the copper doped (Jain *et al.* 2018). This was not surprising since similar magnetization changes had also been reported for copper doped alloy films (Khan *et al.* 2016).
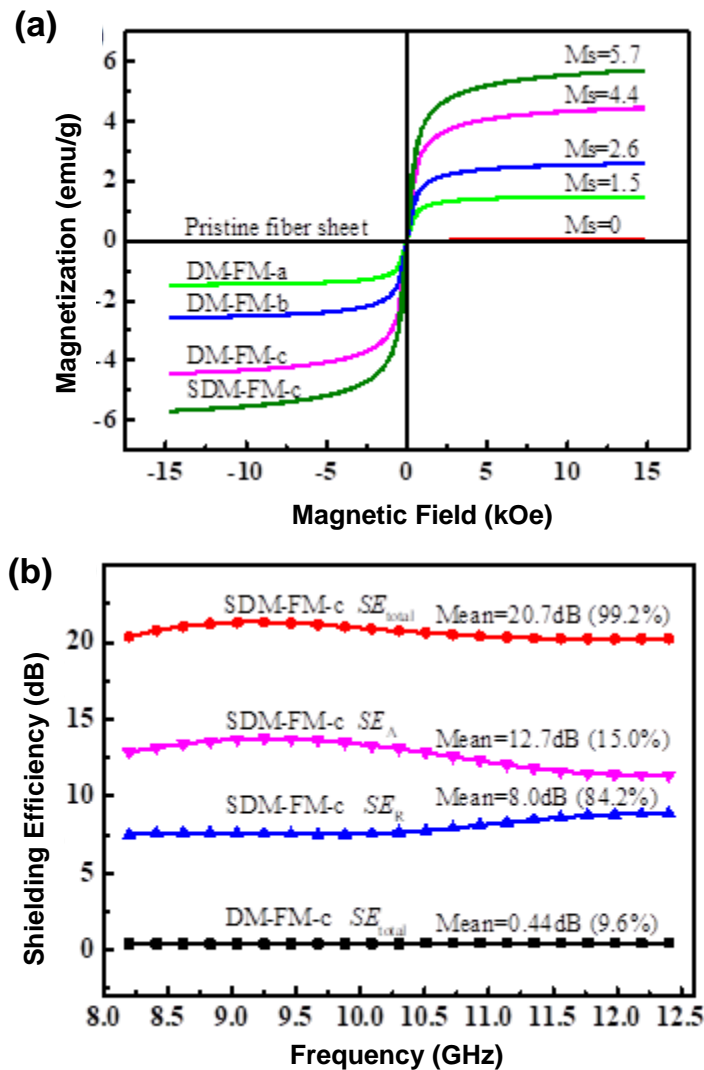

(a)

(b)

Fig. 7. Vibrating sample magnetometer spectra (a) and EMI shielding effectiveness of the magnetic composites (b)

The EMI shielding performance was analyzed by determining the shielding effectiveness (SE) (Fig. 7b). As shown in Fig. 7b, after sputtering the copper films, the EMI SE increased from 0.44 to 20.7 dB, which indicated that approximately 99.2% of electromagnetic energy was effectively shielded by the magnetic composites. The EMI shielding mechanism was studied by comparing the contributions of the reflected and absorbed powers to the incident power. Compared to a 15.0% power loss due to absorption, up to 84.2% of the incident power was attenuated by reflection, which demonstrated that the EMI shielding of the magnetic composites was wave-reflection dominant (Lv *et al.* 2016; Zhao *et al.* 2016). This could be attributed to the sputtered thin copper film with a high complex permittivity and a low complex permeability (Qiang *et al.* 2015; Bera *et al.* 2017; Liu *et al.* 2018). Thus the developed composites could have enormous potential in electronic and building applications, such as circuit/coating constructions.

bioresources.com

CONCLUSIONS

1. A novel natural fiber-based magnetic composite with a sandwich structure was developed in this work. It is comprised of a composite interlayer containing natural fibers and iron oxide, and two outer layers deposited with a thin copper film. The iron oxide loading content was controllable and could be as high as 11.2%. This high loading content was contributed to the abundant pore structures in the fiber matrix, which allowed for greater iron oxide loading amounts.

2. The magnetic composites exhibited a gradient interlayer with a smaller iron oxide particle size of *ca.* 135 nm and a total iron oxide content of 18.7 wt.% for the core layer, and an iron oxide particle size of *ca.* 492 nm in size and a total iron oxide content of 26.1 wt.% for the interlayer surface, which also constructed a metallic texture and supported the thin copper film magnetron sputtering.

3. The formed sandwich structure demonstrated a positive effect on improving the targeted properties. The resulting composites exhibited good thermal stability (maximum degradation rate at 360 °C), surface hydrophobic property (water contact angle of 133°), magnetic responsivity (saturation magnetization of 5.7 emu/g), and electromagnetic interference shielding performance (99.2% of the electromagnetic energy was shielded with a thickness of 0.8 mm).
