Coating Activated Carbon from Coconut Shells with $\text{Co}_3\text{O}_4/\text{CeO}_2$ for High-Performance Supercapacitor Applications: An Experimental Study

Krittiya Chopngam, Montri Luengchavanon, Matthana Khangkhamano, Kanadit Chetpattananondh, and Warakorn Limbut

Activated carbon from coconut shells is a low-cost, environmentally friendly material that is available for fabricating the electrodes for electric double-layer capacitance supercapacitors. As such, activated carbon derived from coconut shells was coated with $\text{Co}_3\text{O}_4/\text{CeO}_2$, and its electrical and ionic conductivity were evaluated. The ternary technique for selecting materials was systematically investigated with an economical process. The $\text{Co}_3\text{O}_4/\text{CeO}_2$ coating that was formed on the activated carbon coconut shells was deemed $\text{AC-Co}_3\text{O}_4-\text{CeO}_2$. The 90-05-05 composite was the best electrode for electric double-layer capacitance supercapacitors, resulting in high conductivity ($0.62 \text{ S·cm}^{-2} \times 103 \text{ S·cm}^{-2}$), low series resistance and internal resistance (based on the Nyquist plot), and the charge-discharge was able to reach 5.60 V for 90 seconds (1A/g). Therefore, activated carbon coconut shells coated in $\text{Co}_3\text{O}_4/\text{CeO}_2$ can promote the necessary characteristics of electrodes needed for electric double-layer capacitance supercapacitors.

INTRODUCTION

Supercapacitors are highly efficient novel green energy storage devices. According to the electrochemical energy storage mechanism, a supercapacitor is, in the terms of electric double-layer capacitors (EDLCs), the best for electrical storage. The EDLCs primarily store energy by the adsorption of electrostatic charges on the porosity of the electrode surface. Due to the fact that EDLCs can be operated under a charge-discharge process that does not activate the chemical charges of substances, these processes enable long service life. While electrode materials are important in determining high-efficiency supercapacitors, the high performance of EDLCs should involve the use of good electrode materials that have a high specific surface area, high porosity structure, and high electrical conductivity (Zhai et al. 2021). The electrons, i.e., energy, are stored in a carbon-based electrode by the collection of opposite charges on either side of the electrode/electrolyte that is separated by an electric double layer structure (Sesuk et al. 2019).
Biomass-waste materials applied as an electrode for supercapacitors, based on activated carbon (AC) from coconut shells, have been reported to result in higher quality electrodes compared to other sources (Sesuk et al. 2019). Southern Thailand has an agriculture-based economy that is abundant in coconuts. Coconut waste could be an available raw material, with a focus on coconut shells. Biomass transforming technologies includes the conversion into activated carbons, which can be utilized for multiple applications (Nguyen et al. 2021; Yağmur and Kaya 2021; Yusuf et al. 2021). In this investigation, activated carbon from coconut shells was formed into the electrode for a supercapacitor. Activated carbon from coconut shells can generate a high surface area (Dandekar et al. 2005), a highly porous composite, and high KOH electrolyte activation. This combination can show a high rate of performance in terms of symmetric supercapacitors (Yin et al. 2016).

Many researchers have used Co$_3$O$_4$ and CeO$_2$ composites for fabricating electrodes in supercapacitors that could enable high performance electrochemistry. Additionally, the Co$_3$O$_4$ and CeO$_2$ composites have been increasingly prepared with nanoparticles or fibre and the pure chemistry for highly-efficient supercapacitors (Aravinda et al. 2013; Kim et al. 2016; Wei et al. 2017; Li et al. 2018). The nanoparticle composites represent high cost production, and the reliance on pure chemistries results in low environment-friendliness.

However, activated carbon from coconut shells has a low electrical conductivity and low ionic transfer, which are necessary properties of a supercapacitor. Cobalt oxide (Co$_3$O$_4$) has been reported to have high electrochemical activity, good electrocatalytic properties (Nguyen et al. 2021), and increases the electrical conductivity of active materials (Pandolfo et al. 2010). In addition, cerium oxide (CeO$_2$) has shown the ability to easily generate oxygen vacancies to further improve ionic conductivity; CeO$_2$ can reverse the oxidation state of Ce$^{4+}$ and Ce$^{3+}$, which can transform these two stable ions and therefore promote rapid electron migration and ion diffusion (Pant et al. 2019).

This study investigated a novel and low-cost electrode composite for a symmetrical supercapacitor. The novel electrode composites used activated carbon from coconut shells and improved the electrical and ionic conductivity by coating it with Co$_3$O$_4$ and CeO$_2$. The ternary technique was used to determine the optimal ratios among AC, Co$_3$O$_4$, and CeO$_2$ for high efficiency, environment-friendliness, and low cost, based on EDLC supercapacitor applications.

**EXPERIMENTAL**

**Materials**

In this investigation, the coconut shells used as raw materials to produce the activated carbon were obtained from Green Carbon Hatyai Co., Ltd, (Thailand), which was followed by physical activation. The coconut shells were activation-heated at a temperature of 1000 °C, for 40 min under an O$_2$ gas mix super-heated steam flow. After that, the samples were cooled to room temperature. The activated carbon was washed with deionized water until the pH value was 7, followed by heat drying at a temperature of 90 °C for 12 h. The activated carbon was pulverized in a ball mill, and then sieved to obtain particles with sizes between 10 μm to 15 μm. The proximate analysis revealed 87.61 wt% fixed carbon that fabricated high carbon in the AC-coconut shell (Abdeljaoued et al. 2018), as shown in Table 1.

Fig. 1. Schematic for preparation of (AC-Co₃O₄-CeO₂) electrode

Preparation of Supercapacitors

Figure 1 shows a schematic of the electrode solution, which was prepared by mixing wt% of activated carbon (AC) from a coconut shell mixture, (Co₃O₄) cobalt (II, II) oxide, and (CeO₂) cerium (IV) oxide (AC-Co₃O₄-CeO₂) in a 0.85 to 0.05 to 0.10 ratio (85-10-05) and a 0.90 to 0.05 to 0.05 ratio (90-05-05) as a conductive agent and 5 wt% of polytetrafluoroethylene (PTFE) as a binder (Alfa Aesar, Haverhill, MA) in 10 mL of ethanol. This solution was then mixed via ultrasonic treatment for 30 min and ground in a ball mill until a homogeneous solution was formed for 24 h. The slurry was used evenly with a doctor blade for painting on a 1 cm x 1 cm silver sheet with a thickness of approximately 200 μm. Carbon electrodes which contained activated materials were available. Thereafter, the electrodes were dried at a temperature of 90 °C for 6 h under vacuum to remove the solvent and eliminate any superfluous anhydrous ethanol. A 0.1 Mol KOH aqueous electrolyte solution was adopted as the electrolyte for the supercapacitors.

Experimental Techniques

The activated carbon samples were characterized via scanning electron microscope SEM. The analysis was conducted with a Quanta 400 (SEM-Quanta) used for observing the surface morphology of the activated carbons. To determine the surface area and pores of the activated carbons, nitrogen adsorption-desorption isotherms were measured and carried out at a temperature of 77 K by employing an ASAP 2460, ASAP 2060, (Micromeritics, Norcross, GA) device; the specific surface areas were calculated using the Brumauer–Emmett–Teller (BET) method.
The X-ray diffraction (XRD) patterns were generated with an Empyrean, PAN analytical diffractometer (WI-RES-XRD EMPYREAN-001, Malvern Panalytical, Malvern, United Kingdom using Cu-Kα radiation within a 2θ range of 10° to 80° (λ = 0.154 nm).

The electrochemical measurements, e.g., cyclic voltammetry (CV) and charge-discharge characteristics, were performed using a workstation (Metrohm Autolab B.V., Utrecht, Netherlands) with a typical three-electrode cell set-up connected to a lab system (potentiostat/galvanostat with NOVA 1.11 software). An Ag/AgCl electrode served as a reference electrode, and a platinum wire served as a counter electrode. The four-point probes measured the electrical DC conductivity using a Mitsubishi Chemical Analytech, Loresta-GX (MCP-T700, Tokyo, Japan). The electrolyte was a 0.1 Mol KOH aqueous solution. To investigate the electrochemical performance of the activated carbons, the voltage window and scan rate were set to be -0.2 to 0.6 V and 10, 20, 50, and 100 mV/s, respectively.

Electrochemical impedance spectroscopy (EIS) was performed using a sine wave of 10 mV over a frequency range of 0.1 Hz to 100 kHz controlled by a Metrohm Autolab B.V. (Utrecht, Netherlands). The proximate analysis used a LECO Macro TGA (TGA 701, St. Joseph, MI). Fourier Transform Infrared Spectrometer (FTIR) was used to analyse composites (Vertex 70, Bruker, Germany).

**Ternary Techniques**

Figure 2 shows the ternary technique used to determine the ratios of AC, Co₃O₄, and CeO₂, respectively. The AC materials must be primarily used in the composite, while the Co₃O₄ and CeO₂ were a minor portion of the composite based on the wt% for the electrode in the supercapacitor, which selected all composites on the top of the ternary analysis. The ternary was determined in the first phase using an orange colour circle and the second phase using a purple colour circle to measure the electrical conductivity via DC four-point probes for comparison.

![Ternary Technique Diagram](image)

**Fig. 2.** The ternary technique used to determine the ratio of AC, Co₃O₄, and CeO₂ in the composite
RESULTS AND DISCUSSION

Figure 3 shows the electrical DC conductivity of composites of various AC-Co$_3$O$_4$-CeO$_2$ ratios (wt%) that were measured and compared to pure AC materials and the supercapacitor electrode standard (Green Cap) produced from nano-graphite. Pure AC is the activated carbon from coconut shells, which had low conductivity when compared to standard electrode supercapacitors. The properties of the electrodes belonging to a supercapacitor should be highly conductive in order to reduce loss in the power source (Zhai et al. 2021). The inclusion of Co$_3$O$_4$ and CeO$_2$ can increase the activated electric and ionic conductivities of a material (Kim et al. 2015; Xing et al. 2020). Therefore, Co$_3$O$_4$ and CeO$_2$ were selected to coat pure AC to provide high conductivity; the optimal systematic ratio was determined via the ternary technique, as shown in Fig. 2.

During the first phase, the electrical DC conductivity of composites with a 90 to 05 to 05, 80 to 10 to 10, 70 to 20 to 10, and 70 to 10 to 20 ratio (AC to Co$_3$O$_4$ to CeO$_2$) was measured. The composites with a 90 to 05 to 05 and 80 to 10 to 10 ratio showed the highest conductivity values ($0.62 \times 10^3$ S·cm$^2$ and $0.52 \times 10^3$ S·cm$^2$, respectively). During the second phase, the electrical DC conductivity of the composites with a 85 to 10 to 05, and 85-05-10 ratio was measured, which resulted in conductivities of $0.46 \times 10^3$ S·cm$^2$ and $0.44 \times 10^3$ S·cm$^2$, respectively. The composite with a 90 to 05 to 05 ratio resulted in a conductivity of $0.62 \times 10^3$ S·cm$^2$, which was close to the electrode standard, with a conductivity of $0.70 \times 10^3$ S·cm$^2$. The composites with 85 to 10 to 05 and 85 to 05 to 10 ratios did not result in a greater conductivity value than the 90 to 05 to 05 composite. Generally, the electrical conductivity depended on the amount of Co$_3$O$_4$ in the composite, but small amounts of Co$_3$O$_4$ and CeO$_2$ can induce catalytic activity and promote electron transfer (Khan et al. 2016; Yu et al. 2018). The carbon coated with Co$_3$O$_4$ and CeO$_2$ can provide high electrical conductivity and greatly promote charge transfer (Li et al. 2019b). However, this investigation was focused on using the maximum amount of AC from coconut shells and minimal additional chemicals, since this study is based on being environmentally friendly and low cost. Therefore, the composites with a 90 to 05 to 05 and 85 to 10 to 05 ratios were selected for further study in terms of suitability as an electrode for EDLC supercapacitors.

![Fig. 3. The composites of various AC-Co$_3$O$_4$-CeO$_2$ ratios (wt%) were measured for electrical DC conductivity compared to pure AC materials and the supercapacitor electrode standard (Green Cap)](image-url)
Figure 4 compares the XRD patterns for pure AC-coconut shell and composites with a 90 to 05 to 05 and 85 to 10 to 05 ratio. Fig 4a and 4b shows the diffraction peaks of composites with a 85 to 10 to 05 and 90 to 05 to 05 ratio at 2θ values of 31.266°, 36.841°, 59.348°, 68.618°, 78.393°, and 90.955° related to the (220), (311), (511), (531), (622), and (642) planes of Co$_3$O$_4$ (ICSD:01-078-1969), respectively. These composites revealed diffraction peaks at 2θ values of 28.548°, 33.082°, 47.485°, and 76.704°, corresponding to the (111), (200), (220), and (331) planes of CeO$_2$ (ICSD:01-075-9470), respectively. In addition, these composites exhibited diffraction peaks at 2θ values of 17.990°, 29.391°, and 33.215° corresponding to the (101), (200), and (112) planes of KCo (HCOO)$_3$ (ICSD:01-080-4584), respectively. Furthermore, these composites also showed diffraction peaks at 2θ values of 35.468°, 53.478°, and 57.008° corresponding to the (311), (422), and (511) planes of Fe$_3$O$_4$ (ICSD:01-080-4584), respectively. The XRD of the AC-coconut shell (as shown in Fig. 4c) reveals that the diffraction peaks of carbon at 2θ values of 26.586° and 44.664° correspond to the (002) and (101) planes of carbon (ICSD:01-083-6084), respectively. These carbon peaks also appeared in the XRD patterns of the composites with 85 to 10 to 05 and 90 to 05 to 05 ratios.

The graphene oxide (C) and Fe$_3$O$_4$ can be fabricated for nano-composites from coconut shells (Rukman et al. 2019). Coconut shell contains soil elements, e.g., oxygen (O), carbon (C), hydrogen (H), calcium (Ca), and potassium (K) (Sujiono et al. 2020). Therefore, the XRD patterns of the composites with 85 to 10 to 05 and 90 to 05 to 05 ratios generated peaks for KCo (HCOO)$_3$, which activated the Co$_3$O$_4$, H, and K for a chemical reaction in the electrode composites.
Figure 5 shows the FTIR spectra of original AC-coconut shell modified by Co$_3$O$_4$ and CeO$_2$ in terms of ratios of 90 to 05 to 05, and 80 to 10 to 10. The aromatic structure of AC-coconut shell was shown to be around 1577 cm$^{-1}$ (C=C vibration) and 1184 cm$^{-1}$ (C-C stretching). The C-O stretching was found at around 1215 cm$^{-1}$. Furthermore, the AC-coconut shell showed the broad peak at around 3435 cm$^{-1}$ and peak at around 1633 cm$^{-1}$, corresponding to the stretching vibration and the bending mode of hydroxy groups, respectively. These two peaks dropped after being doped with Co$_3$O$_4$ and CeO$_2$, specifically at ratios of 90 to 05 to 05. It appears that the Co$_3$O$_4$ and CeO$_2$ bonded with the structure of AC-coconut shell (Jayakumar et al. 2019). The bridging vibration of O-Co-O bond was indicated clearly at around 662 cm$^{-1}$ in both cases of adding Co$_3$O$_4$. The CeO$_2$ stretching vibration in the structure and Ce-O bending vibration were represented in the same wavelength range of around 570 cm$^{-1}$ (Prabaharan et al. 2017; Jayakumar et al. 2019).

The FTIR spectra can indicate the modification of AC-coconut shell, which shows similar adsorption peaks, revealing original and modified activated carbon by coated Co$_3$O$_4$ and CeO$_2$. However, the composites are modified by Co$_3$O$_4$ and CeO$_2$, which destroys the organic structure. Further, the acidic group was enlarged during the chemical modification process.

Table 2 shows the surface area parameters of the AC coconut shell compared to the electrode material standard and the 90-05-05 and 85-10-05 composites. The surface area and pore volume properties were ranked as follows: the electrode standard was greater than the AC coconut shell, which was greater than the 90-05-05 composite, which was greater than the 85-10-05 composite. The average pore width properties were ranked as follows: 90-05-05 composite, was greater than the electrode standard, which was greater than the 90-05-05 composite, which was greater than the AC coconut shell, respectively. The electrode standard had a higher surface area and pore volume since it was produced from nano-graphite materials.

The AC coconut shell had a surface area of 2100 m$^2$/g, a pore volume of 0.153 cm$^3$/g, and an average pore width of 22.34 Å, which was dependent on the procedure used to prepare the materials (Suleman et al. 2015). The AC coconut shell composite coated in Co$_3$O$_4$ and CeO$_2$ had lower a surface area and pore volume, but a higher average pore width. These properties may change with different coated particle sizes. The breadth of the particle size distribution can also be affected by the total space, with research demonstrating an increase in the particle size distribution breadth reduces the total space while producing broader void size distributions. Since the particle size can affect the total void volume and void sizes, the particle size distribution can be fabricated to influence the resistance and efficiency of devices using composite electrodes, as shown in Fig. 6 (Rennie et al. 2016).

Fig. 6. Particle size effect on the surface area parameters: (a) mono-size particle; and (b) a broad particle distribution (Rennie et al. 2016)

Figure 7 shows the SEM images of the electrode composites, revealing the porosity and homogenous nature of the composites. Figures 7a to 7c show the SEM images of the AC coconut shell, which had a small and homogenous particle size and a square shape, with a particle size less than 10 μm. Figures 7d to 7f show the SEM images of the 85-10-05 composite, which exhibited a homogenous particle size, a big square shape, and a small spherical shape, with a particle size is 10 μm. Figures 7g to 7i show the SEM images of the 90-05-05 composite which exhibited a homogenous particle size, a big square shape, and a small spherical shape, with a particle size ranging from 10 to 20 μm. The SEM images of the AC coconut shell, 85-10-05 composite, and 90-05-05 composite were related to surface area parameters (Table 2) and the Co$_3$O$_4$/CeO$_2$ coated composites were affected by different particle sizes (Fig. 7).
As the average particle size (3.5 μm to 18.1 μm) in the EDLCs electrodes increased, the internal resistance of the electrode increased, and the rate capacitance decreased. This behavior was generated from the dense packing of the AC found in composites with smaller particle sizes, as the volume of the space substantially increased as the particle size decreased (Yoshida et al. 1996). The trends of resistance and specific capacitance were affected by a wider range of average particle sizes (0.02 to 20 μm). It was found that the electrode of the EDLCs with larger particle sizes showed poorer capacitance retention with an increased discharge rate (Portet et al. 2008). The reducing particle size can easily conduct ionic transfer by reducing the diffusion length of the ions (Tanaka et al. 2012). The 85-10-05 and 90-05-05 composites also produced particle sizes in a range of 10 to 20 μm.

Figure 7. SEM images of the electrode composites: (a, b, and c) AC coconut shell at x350, x1500, and x 3000 magnification, respectively; (d, e, and f) 85-10-05 composite at x350, x1500, and x3000 magnification, respectively; and (g, h, and i) 90-05-05 composite at x350, x1500, and x3000 magnification, respectively

Figure 8 shows the Nyquist plots comparing the AC coconut shell, 85-10-05 composite, and 90-05-05 composite in terms of performance as the electrode in the EDLC cell. The 85-10-05 composite, 90-05-05 composite, and AC coconut shell had similar interval resistance trends; however, the 90-05-05 composite was found to have lower resistance. The semicircle is displayed in the high-frequency region, i.e., the magnified region near the origin in the inset of Fig. 8, and a linear section represented the low-frequency range, which was found to be linear for the 85-10-05 and 90-05-05 composites. The linear section at low frequencies of Nyquist plot reflects capacitance properties (Fig. 8). This result indicated a degree of inhomogeneity in the double layer region that is frequently seen when using porous electrodes (Song et al. 1999).
The inset of Fig. 8 shows the values of the series resistance ($R_s$) that were related to the point where the spectra crosses the real axis. These resistances are generated due to electrolyte conductivity that remained the same in each cell. The $R_s$ values of the 90-05-05 composite, 85-10-05 composite, and AC coconut shell were determined to be 11 $\Omega$, 16 $\Omega$, and 18 $\Omega$, respectively. The semicircle indicated at higher frequencies, internal resistance ($R_i$) is produced via the reactions between the pores of the electrode with the ions conducted in the electrolyte, which can be referred to as the collective distributed resistance (Pandolfo et al. 2010). The AC coconut shell and 85-10-05 composite show semicircles larger than the 90-05-05 composite. Table 2 shows that the pore volume of AC coconut shell was greater than that of 90-05-05 composite, which was greater than that of the 85-10-05 composite, the latter about two-fold. This may be caused by a minor increase in the pore volume that substantially influenced the $R_i$ values.

Figure 9 shows the electrochemical performance of the AC coconut shell, 85-10-05 composite, and 90-05-05 composite evaluated via cyclic voltammetry. Figure 9a shows the cyclic voltammogram (CV) curves, which revealed a large area, indicating better capacitive behaviors. Figure 9b shows the reduction peaks at 0.48 V, 0.50 V, 0.50 V, and 0.52 V, respectively. Figure 9c shows the reduction peaks at 0.48 V, 0.50 V, 0.52 V, and 0.54 V, respectively. Notably, the 90-05-05 composite indicated better reduction peak potentials than the 90-05-05 composite, which was primarily due to the synergies between the active chemicals in the Co$_3$O$_4$ and CeO$_2$ after coating. Moreover, the close contact between the Co$_3$O$_4$/CeO$_2$ and the AC coconut shell layer can act to smooth the charge transfer and enhance the oxygen reduction reaction (ORR) activity. This activity on Co$_3$O$_4$/CeO$_2$ could improve electrical conductivity and high oxygen-storage capacity (Li et al. 2019a). The CV of the 85-10-05 composite and 90-05-05 composite revealed a narrow area and fabricated higher peaks in comparison to the CV of the AC coconut shell, in which the Co$_3$O$_4$/CeO$_2$ reacted clearly with the reduction peaks in the AC composite.
Fig. 9. Cyclic voltammogram for (a) the AC coconut shell; (b) the 85-10-05 composite; and (c) the 90-05-05 composite in a KOH solution at various scan rates.
Figure 10 shows the charge-discharge characteristics for different composites using a current density of 1 A/g. The voltage potentials corresponded to the CV between -0.2 and 0.6 V, which demonstrated that the charge time drastically affected the various materials. The peak of the 85-10-05 composite, AC coconut shell, and 90-05-05 composite was reached at 5.20 V, 5.50 V, and 5.68 V, respectively. The 90-05-05 composite was found to have the charging potential sufficient to reach a higher voltage. The AC coconut shell composite, when coated with Co$_3$O$_4$/CeO$_2$, can decrease the charge-discharge time due to the sluggish kinetics of the reduction reaction to fast potential change (Li et al. 2019a; Pant et al. 2019). Many factors, e.g., conductivity, specific surface area, and pore size, can affect the electrochemical capacitance of an electrode material (Gao et al. 2012). Co$_3$O$_4$ is a spinel oxide whose cation production can be fabricated to produce Co$^{2+}$(Co$^{3+}$)$_2$(O$^2$)$_4$. The Co$^{2+}$ ions are colonized in the tetrahedral site, and the Co$^{3+}$ ions are colonized in the octahedral site. These two ion charge states can exchange in a small amount among the two sites, which describe the electric properties of stoichiometric Co$_3$O$_4$. In addition, Co$_3$O$_4$ is an intrinsic p-type semiconductor with electric conductivity, which is mostly due to its being a hole-free carrier (Makhlouf et al. 2013). The increasing amount of Co$_3$O$_4$ in the AC composite can be evaluated for conductivity but may not depend on the quantity. While CeO$_2$ is stable, it can react to reversible oxidation states of Ce$^{4+}$ and Ce$^{3+}$ to transform into each other easily and rapidly, generating rapid electron migration and ion diffusion (Xing et al. 2020). The increasing CeO$_2$ can connect the higher ionic transfer between the electrode and electrolytes (KOH) of the EDLCs. Therefore, a Co$_3$O$_4$/CeO$_2$ coating on AC coconut shells that can promote a faster charge potential and the voltage capacity needed to be a high-performance EDLC.

![Fig. 10. Charge-discharge characteristics for various composites using a current density of 1 A/g](image)

**CONCLUSIONS**

1. The development of electrical double layer capacitance (EDLC) supercapacitors using activated carbon (AC) coconut shells has been investigated by many researchers. While nano-AC composites can be utilized for high performance EDLCs, such composites rely on high-technology machinery, a multi-step procedure, and have a considerable cost. Based on the low cost and environmentally friendly nature of this study, the composite must primarily use AC coconut shells.
2. Since the best choice for developing an AC electrode EDLCs supercapacitor is using an applied coating, the ternary technique was used for the systematic selection of the lowest amount of oxide element. $\text{Co}_3\text{O}_4$ and $\text{CeO}_2$ were selected to cause high ionic and electrical conductivity. The ratio of the $\text{Co}_3\text{O}_4/\text{CeO}_2$ coating to AC coconut shells are loaded in wt%, as determined by the ternary analysis in terms of AC to $\text{Co}_3\text{O}_4$ to $\text{CeO}_2$.

3. The 85-10-05 composite and 90-05-05 composite were selected since they used small amounts of $\text{Co}_3\text{O}_4$ and $\text{CeO}_2$, which led to high electrical direct current (DC) conductivity. The 90-05-05 composite had higher performance, with a high electrical DC conductivity of $6.2 \times 10^3 \text{ S cm}^{-2}$ and a surface area of 245 m$^2$/g.

4. The 90-05-05 composite also exhibited a low resistance from the Nyquist plot based on a series resistance ($R_s$) value of 11 $\Omega$, and the internal resistance ($R_i$) generated a smaller semicircle. The CV of the 90-05-05 composite showed high peaks of electrochemical reduction in all rate scans. In addition, the charge-discharge characteristics of the 90-05-05 composite was able to reduce the charge-discharge time to 90 s with a higher potential of 5.60V (at 1 A/g).

5. The AC coconut shell was coated with $\text{Co}_3\text{O}_4/\text{CeO}_2$, which resulted in electrical and ionic conductivity. As such, a small amount of $\text{Co}_3\text{O}_4/\text{CeO}_2$ coating on AC coconut shells is low in cost and can easily be processed for producing electrodes for EDLC supercapacitors.

ACKNOWLEDGMENTS

This research was financially supported by the Higher Education, Center of Excellence in Materials Engineering (CEME), the Energy Technology Research Center (ETRC), the Graduate Engineering Scholarship and the Graduate school scholarship from the Prince of Songkla University. The authors would also like to thank the Department of Mining and Materials Engineering, Faculty of Engineering, Prince of Songkla University for facility support.
